Mr. Fleming, who made a series of experiments to determine the changes accomplished in antiseptic ligatures, says:—"The results[2] of these experiments show that a gradual softening takes place from without in, the catgut breaking down and becoming infiltrated with cells, probably leucocytes; . . . next, the pultaceous mass into which it has been converted begins to metamorphose, and is soon permeated with blood-channels and ultimately may be described as a cast of the catgut in a kind of granulation tissue freely supplied with bloodvessels which, in many of my sections, were freely injected." It is a well-established fact that epithelial cells, far removed from the circulation and actually dead, placed in contact with a granulating surface, live again and multiply; and there seems no reason why the cells of the fibrous tissue of the sheep should not also. Ivory pegs driven into bone become absorbed; metals, glass, wood, and silk ligatures may remain in the tissues for an unlimited time without exciting irritation, inflammation, or suppuration.

The question as to the special value of carbolized catgut remains open since the facts above stated of wood, metal, silk, glass, etc., are well established. Prof. Paul F. Eve, of Nashville, Tenn., informs me that for

ligature of animal tissue antiseptically upon an artery, whether tightly or gently, we virtually surround it with a ring of living tissue, and strengthen the vessel where we obstruct it. The surgeon, therefore, may now tie an arterial trunk in its continuity close to a large branch, secure alike against secondary hemorrhage and deep-seated suppuration, provided always that he has so studied the principles of the antiseptic system, and so carefully considered the details of the mode of dressing best adapted to the particular case in hand, that he can feel certain of avoiding putrefaction in the wound. For my own part, I should now, without hesitation, undertake ligature of the innominate, believing that it would prove a safe procedure.

[1] Prof. Lister, in the Discussion which followed the reading of this paper, objected to the position in which he had been placed in reference to the organization of the ligature antiseptically applied, and the following explanation was subsequently made by the author: "It is due to Prof. Lister, due to the Surgical Section, and due to myself that I should correct a misstatement of the position of Prof. Lister in regard to ligatures antiseptically applied. In the Report on Antiseptic Surgery, in the part relating to the use of the antiseptic ligature, the following passage occurs: Prof. Lister says, 'Ample as was the evidence afforded to the naked eye of the organization of these ligatures, it was satisfactory to find it confirmed in the clearest manner by the microscope,' . . . and again, 'It appears, then, that by applying a ligature of animal tissue antiseptically upon an artery, whether tightly or gently, we virtually surround it with a ring of living tissue and strengthen the vessel where we obstruct it.' These are the precise words of the report, and the precise words of an article On Ligature of Arteries on the Antiseptic System, by Joseph Lister, Esq., F.R.S., Professor of Surgery in the University of Glasgow, as published in the London Lancet for April 3, 1869, page 451, and copied into Braithwaite's Retrospect, vol. lviii., 1869, pp. 139, 140. So far, it would appear that in the Report on Antiseptic Surgery I was entirely correct in my quotation of Prof. Lister's language, as it appeared in print; but Prof. Lister having stated in the Surgical Section that he had not advocated the theory of the revitalization of the antiseptic ligature, I must accept his statement as correct, and modify my report accordingly. The quotation embraces but two sentences of an elaborate article, a careful reading of which, prompted by Prof. Lister's disclaimer, permits me to conclude that the expression, 'the organization of these ligatures,' is not intended to convey the thought that the tissues of the ligature are revitalized, but that a living tissue takes the place of the absorbed ligature; and that the expression, 'a ring of living tissue,' does not refer to a revitalization of the tissues of the ligature, but to a new tissue occupying the former site of the catgut, as if cast in its bed."

[2] The Behavior of Carbolized Catgut inserted among Living Tissues; by Wm. J. Fleming; Lancet, May, 1876.

forty years he has been in the habit of using the sinews of the deer for ligating vessels. He says: "I have never used carbolized spray or ligatures. The tendons of the deer, dried and torn into shreds and rolled into ligatures, are what I employ. They are absorbed, and I have never seen a knot made in tying a vessel. I have occasionally used them as sutures, but generally apply silk for this purpose." Dr. Eve's experience with the tendons of the deer leaves us free to conclude that the carbolized oil and water with which Prof. Lister's catgut is prepared has no special value in preventing suppuration or hastening absorption.

The following propositions are sustained by our present knowledge of the subject of Antiseptic Surgery:—

I. Putrefaction may and does occur in the solids and liquids of the body both with and without the direct contact of germs borne in the air or water. In sustaining this proposition, I need only call attention to the innumerable abscesses containing fetid pus that may occupy any site within the human body, sites so remote from all the mucous and cutaneous surfaces that neither air nor water as such can reach them.

II. Putrefaction of the solids and liquids of an open wound may in many cases be prevented by not permitting the contact of living germs with the surface, or by destroying their vitality after contact with it. The experiments made by Prof. Tyndall are so conclusive that to deny their force and completeness seems irrational. If they were negative, or if they were few, a question might arise, but being positive and almost innumerable, there seems no reasonable doubt of the correctness of his conclusions. In his admirable series of experiments he allowed the floating particles to settle from the air until it was optically pure, and found that infusions placed in this pure air did not undergo putrefaction, and that living organisms were not produced. There are many agents by which the vitality of septic germs may be destroyed; and their contact with the cut surfaces is sufficient to destroy the vitality of such germs as may be present at the moment. While it is exceedingly difficult in the case of an open wound to prevent the contact of septic germs that pervade the atmosphere, it may generally be accomplished for a brief period. And while there are many substances that efficiently destroy the vitality of septic germs, the profusion in which they exist renders it necessary that the applications for their destruction shall be so precisely made, and so frequently renewed, that it will in practice rarely be accomplished.

III. It is possible that the living solids and liquids of the body may be so altered that they shall not furnish the conditions necessary to putrefaction. Polli's experiments with the sulphites afford evidence of the truth of this proposition. For he found that the bodies of dogs fed with the sulphites did not decompose, and that urine passed during the administration of sulphites did not putrefy.

IV. Practically, the conditions to be met in preventing putrefaction are so difficult, that in many cases it is impossible to comply with them; yet even partial success is eminently worthy of our best efforts. In the experiments made by Prof. Tyndall, in which he determined the presence of germinal protoplasm in the air, it appears that several days of absolute quiet are necessary for the complete settling of the germs so that the air becomes free from them. These particles of living matter are so infinitely minute[1] that they are utterly beyond the reach of the

[1] Spontaneous Generation Controversy, by Rev. W. H. Dallinger; Monthly Microscopical Journal, vols. x. and xiii. See Popular Science Monthly.

microscope, and can only be made visible by a condensed beam of light. Dallinger and Drysdale have shown that, while the life of the monad will not resist a temperature of 140°, the germs that Prof. Tyndall recognized by his electric beam are capable of germinating after having been subjected to a temperature of 300°. In view, then, of these facts, and the one established by Pasteur, that putrefaction occurs only in the presence of living germs, and that Prof. Fischer has uniformly found bacteria under antiseptic dressings so ingeniously devised as those of Prof. Lister, we must conclude that germs cannot be prevented from coming in contact with wounds. While this is true, the rapidity of putrefactive changes may be diminished, the absorption of septic matters limited, and the eliminative functions stimulated so that septicæmia may not occur.

In conclusion: Putrefaction does not occur in the absence of living organisms; this fact was established by Pasteur and is supported by Tyndall.

The germinal matter active in putrefactive changes is found abundantly in air and water; most conclusive evidence of this fact is furnished by the experiments of Tyndall and Rindfleisch.

The germinal matter resists exposure to a temperature of 300°, while monads cease to manifest vital phenomena after exposure to 140°; the experiments of Dallinger and Drysdale are presented to sustain this position.

Septicæmia is induced by the presence of the products of putrefaction in the blood; the precise element which causes by its presence septicæmia is not determined.

Professional experience teaches, and the experience of Billroth demonstrates, that absorption of putrefactive products does not occur with sufficient rapidity from a granulating surface to produce blood-poisoning.

Hence, in the early stages of the healing of injuries, septicæmia is more to be feared than after granulations have been formed; and the danger in this period is heightened by the presence of dead and decomposing fragments of original tissue.

Antiseptics may simply strain out the catalytic germs, as cotton-wool; or destroy the germs, as carbolic acid, salicylic acid, the salts of copper, zinc, mercury, etc.

Antiseptics may destroy the products of putrefaction, as iodine, bromine, chlorine, and permanganate of potassium, etc.

Antiseptics may alter the putrescible matters so that putrefaction cannot occur, as sulphurous acid, etc.; or antiseptics may alter the tissues of a wounded surface so that, though septic matters are present, they may not be absorbed, as perchloride of iron, etc.

The rapid removal of septic matter from contact with an absorbing surface will prevent absorption, as is done by the water-bath.

The difficulty encountered by experimenters in preventing the development of infusoria in vegetable and animal infusions, teaches, and the experience of surgeons confirms, the impossibility of invariably preventing the admission of germs to putrescible substances, either in the most carefully constructed reservoirs or on the free surface of the human body.[1]

[1] I am indebted to Drs. Evers and Boutwell for translations from the German, and to Drs. Boisliniere and Lebeau for translations from the French. I must also acknowledge my obligations for the use of the Army Medical Library, at Washington, and of the valuable collection of the College of Physicians of Philadelphia.

Discussion on Dr. Hodgen's Paper.

After the reading of the preceding paper, Dr. Addinell Hewson, of Philadelphia, said:—I have been for many years interested in the subject of Antiseptic Surgery, and have tried almost every substance which has been introduced for the purpose of destroying germs. I have relied principally of late upon *earth*, as I am satisfied that *dryness* is the most essential element in any dressing. As Prof. Hodgen has said, water produces germs rapidly, and it is impossible to prevent this even with powerful antiseptic agents. I have therefore, during the past year, at the Pennsylvania Hospital, absolutely prohibited the washing of any wound during its entire treatment. In addition to dry dressings, it is important to remember that there are other necessary conditions for rapid healing, and I have not used a ligature in the Pennsylvania Hospital for ten years, employing always either acupressure or torsion, and thereby avoiding foreign bodies in the wound. I also enjoin quietude of the parts, with infrequent changes of dressings; I have also tried the effect of color, by covering wounds with blue paper, to exclude all but the actinic rays. For six months I have tried salicylic acid, sprinkling it freely upon the wound, and covering the latter with cotton-wool and then with blue paper. I never wash wounds nor disturb the dressing save to remove the outer layers when they are soiled. The salicylic acid produces no pain, but acts as a sedative, so much so that at first I thought it was narcotic, but I subsequently found this to be an error. I am seldom obliged to give morphia, but, to satisfy the patient, have tried hypodermic injections of a fluidrachm of cold water, a remedy which I have also found successful in relieving sciatica. I have partially superseded earth by salicylic acid, but have not abandoned the former, save when the prejudices of patients or nurses have thrown obstacles in the way of its successful employment.

Dr. J. H. Pooley, of Columbus, Ohio, said:—I have come to consider carbolic acid as important in surgery as instruments themselves. I have known large ragged wounds to heal under its application without one drop of pus. I have found the most efficacious form to be one part of carbolic acid to seven of olive oil, which is less offensive than linseed oil. I always make the application with a brush, carrying the oil well down into every portion of the wound, then applying lint saturated with the same mixture, and retaining all with a bandage. This should be repeated every twenty-four hours, brushing the oil in thoroughly, and removing all sloughs. I have recently seen an extensive crush of the soft tissues of the foot heal, without discharge, in three weeks under this dressing, while under ordinary circumstances the cure would have occupied two or three months. It must be added that, while carbolic acid for a time assists the healing process, yet after a certain period it seems positively to retard cicatrization, pointing to the possibility that this acid has the same repressing power upon granulations that it has upon germs. I have had but little experience with salicylic acid, but in one case in which I used it upon an immense mass of granulations situated over the region of the liver, and from which had been discharged a large number of gall stones, the dusting of the surface occasioned severe pain, an opposite effect to that described by Dr. Hewson, who has stated that the application is painless.

Dr. Hewson said:—In amputations, when I close the wound with a covering of powdered salicylic acid and cotton-wool, there is no pain; but the same dressing in open wounds does give pain. I should add that I always close the wound, not with adhesive plaster, but with strips of gauze and collodion, which is less irritating and favors primary union, besides giving the advantage of a visible wound, and preventing the direct contact of the salicylic acid or earth.

Dr. William Canniff, of Toronto, Canada, said:—It is, I believe, very generally acknowledged that the air is inhabited by various forms of germs—

organisms possessing different degrees of vitality; but it remains a question whether putrefaction is due to the operation of these microscopic organisms. Dr. Hodgen's first proposition states that "Putrefaction may and does occur in the solids and liquids of the body, both with and without the direct contact of germs found in the air or water." Well, if that is the case, I submit that the doctrine urged by Prof. Lister is undermined.

Dr. Hodgen said:—I did not intend to convey the meaning that germs are not present in all cases of putrefaction. The organisms may be introduced to the part through the blood.

Dr. Canniff said:—Then what is the use of applying to a wound or open abscess means to form a barrier to the ingress of germs? If organisms can enter the system through the lungs, or any other mucous surface, and find their way to a certain part to work mischief, it is entirely futile to adopt any procedure to prevent their action. I should like to ask the advocates of the germ theory if they hold that organic matter can never putrefy without the operation of air germs? Because if it ever does, it would be difficult in any given case of putrefaction to show that this was not a simple chemical change in the elements composing the dead animal matter. It is a received doctrine that the body is made up of an infinite number of cells, or molecules, each of which possesses a distinct individual life. They have a moment of birth, and a period of growth and development, of maturity, of decline, and of death; and during their period of life they, like the whole body, are subject to disease, and to degeneration; they may be feeble, or possessed of vigorous vitality. They are also individually and in number liable to injury. Take a contused wound; in it may be found a number of cells crushed to death; others are injured in various degrees, some of which will or may under favorable circumstances recover and be completely or partially restored to their normal vitality. Which must perish and which shall be restored, has to be determined by nature. The line of demarcation has to be established; and the cells deprived of life sequestrated. This is a work of time, and is accomplished by natural laws. I am unable to see in what way the presence of germs can affect this procedure. If a portion of tissue is crushed to death, beneath it is carried out the work of sequestration; and this is attended with chemical changes in the dead organic matter. It is asking a good deal to expect us to believe that this is due to air germs.

My own experience is such that I find it impossible to entertain the doctrine of germ putrefaction. I will mention three cases in my own practice: A man of over sixty had his leg crushed by a wagon heavily laden. There was a compound dislocation of the knee-joint, with fracture of the upper extremity of the tibia. The limb was placed in a proper position, the parts adjusted, and cold water dressing alone applied. The wound was freely and constantly exposed to the air; and, although the weather was hot, the wound healed, and the man recovered with perfect use of the joint and with no suppuration whatever. Two men, injured at the same time by a railway accident, were brought into the Toronto General Hospital. One had contused wounds of the leg. Cold water dressing was employed; and he made a rapid recovery. The other man, in a bed beside the first, had severe contusions of the leg, but no wound. The skin was unbroken. In a number of days it was found that suppuration had taken place. The abscess was opened, and forth came putrefying pus. Now here the putrefaction must have taken place without the presence of germs, or else they had been exceedingly active in finding their way through a mucous surface and by the blood to the part. I may say that the practice recommended by Prof. Lister has not been adopted in the Toronto Hospital; his doctrine is not as yet acted upon; and I feel safe in saying that the success attending the treatment of wounds in that Institution is not exceeded by that in any other. Of course, in hospitals and other places, the organisms which exist in the air are often depraved; they take a low form of degraded life, and the result is an impure air which will more or less affect open tissue;

but I am referring to ordinary air. I have in hundreds of cases seen incised wounds, many in connection with plastic operations, in which healing by primary adhesion has taken place, and yet in which no care has been taken to keep away supposed germs. Often the wound is allowed to remain open for some time, until all oozing of blood has ceased. Now how are we to account for these results, if the air is everywhere peopled by organisms bent on working destruction whenever a solution of continuity takes place on the surface of the body?

In speaking of the treatment pursued in the Toronto Hospital, I do not intend to convey the impression that the agents called antiseptics are not used. They are constantly employed for purifying tissue, not with the view of destroying or preventing the action of air germs, but to arrest or prevent putrefying decomposition due to chemical changes. In conclusion, I would say that I believe that everything, almost, depends upon *cleanliness* in the management of wounds; and I believe that the success which has been obtained by those who practise according to Prof. Lister's theory, is greatly due to the cleanliness which that practice secures. Next to cleanliness, I think that the maintenance of *rest* is valuable; physical and physiological rest. Rest after the evacuation of an abscess will often secure an early adhesion of the walls of the collapsed sac. *Pressure* again is an important element in the treatment of wounds so as to press away fluid in the part, and to prevent feeble circulation or stagnation of blood in the tissues which have to supply the reparative material. And lastly, attention must be given to the constitution and to the surroundings of the patient. Is it not to be feared that the particular treatment advised by Prof. Lister tends to divert the attention of the surgeon from these essential points?

Dr. F. H. Hamilton, of New York, said:—In common with all the other members of the surgical section, I feel a great interest in what you, Mr. President, will have to say on the subject of antiseptics in surgery. The medical men of this country are familiar with your labors in this direction. They know with how much zeal and intelligence you have prosecuted your inquiries, and I may add for myself, personally, that I have never seen a medical gentleman who had enjoyed the privilege of witnessing your practice in your own wards, who was not delighted with the results. Nevertheless, a large proportion of American surgeons seem not to have adopted the practice; whether from a lack of confidence or for other reasons, I cannot say. We are happy, therefore, that you have this opportunity to address us at this time, and we hope sincerely that you will be able to remove such doubts and practical difficulties as remain in our way. Indeed we would be glad to have you convince us that your method is the best.

It seems necessary to remind the Section, however, that there are in this country and abroad other methods of treating open wounds, for which their advocates claim exceptional and extraordinary results. Recently our attention has been called by a paper read before the American Medical Association, I think at St. Louis, to what is called the "open-air treatment," in which no dressings whatever are employed, but the wound is left open to the air, the discharges being permitted to drop into proper receptacles, or to dry upon the surface. My friend, Prof. Moore, of Rochester, called my attention to a case of amputation at the shoulder-joint treated in this manner in one of his surgical wards, which was closing rapidly and with very little suppuration. At the Bellevue Hospital this method has been employed recently, in quite a number of major amputations, and with remarkable success. It must be noticed that the open-air treatment is the exact opposite of Prof. Lister's antiseptic method, yet there are not a few who claim for it equally good results with those obtained by Prof. Lister. A few years since I was appointed operating surgeon to the St. Francis's Hospital, a hospital of several hundred beds, in the city of New York, where I found Dr. Rose and the other gentlemen (all of whom were German, and thoroughly educated) employing warm water in

the treatment of nearly all surgical accidents. The same plan was pursued by these gentlemen, under my observation, after I became connected with the Hospital, and, I must say, with most extraordinary results. No ointments nor antiseptic washes were used to my knowledge, unless as a rare exception, but the warm water dressings were applied to all open sores, whether simply traumatic or specific, in the form of either baths or fomentations. Under this treatment, pyæmia, septicæmia, erysipelas and gangrene were almost unknown, except as these originated outside of the hospital and before admission to the wards. That is to say, under the warm-water treatment the origin or development of these conditions was almost unknown.

The same plan has been adopted to a certain extent by myself and some of my colleagues in the Bellevue Hospital, and several of the gentlemen, including Prof. Gouley, who I believe is present, have attested its excellence, if not its superiority. My largest and most satisfactory experience, however, has been obtained while occupying the position of Surgeon-in-Chief of the New York Reception Hospitals. The results have been given to the profession in a couple of papers, one of which was published in the Richmond and Louisville Medical Journal, in 1874, and the other in the Medical Record of New York, during the same year; but the most complete essay upon the subject was published, in 1875, by my former pupil, Dr. Frederick E. Hyde, of New York, in the Buffalo Medical Journal, and subsequently in pamphlet form.

There are yet other plans for the treatment of wounds and other surgical accidents, for which their advocates have made special claims, all of which may be considered as contending with the method advocated by Prof. Lister, for respectful consideration, if not for preference.

It may not be possible for this body to decide now between the merits of these several methods, but we shall listen with great interest to what the distinguished gentleman from Edinburgh shall say upon this subject.

Dr. J. A. Grant, of Ottawa, said:—For many years we used cold-water dressings at the Ottawa Hospital, with great success, yet failed to obtain results equal to those secured by Prof. Lister. I therefore made a visit to Edinburgh, and was fully convinced of the superiority of the antiseptic method. I was particularly attracted by the extreme care and cleanliness which characterized all of Prof. Lister's operations.

Dr. R. A. Kinloch, of Charleston, said:—While I am willing to accord to the antiseptic system, carried out in the various ways which have been suggested, all or much that has been claimed for it, I think that *rest* is an important factor in the treatment of wounds, which is too much overlooked, and to which may perhaps be attributed much of the good claimed for certain kinds of dressing. The value of immobility is recognized in the treatment of fractures and joint diseases, but it is equally important in dealing with lesions of the soft parts. The benefits said to have been derived from the use of warm water, may be in part due to the quietude of the limb within the box in which it is placed during the course of treatment. The cotton dressing serves admirably the purpose of securing apposition and immobility of the wounded tissue, and many of the forms of antiseptic dressing are similarly effective, because the dressing is but seldom disturbed. The dirt dressing of Dr. Hewson may do good in the same way; it moderately compresses, supports, and keeps at rest the injured structures. Even the plan now carried out at Bellevue Hospital, of exposing wounds to the air, may act in the same manner. The parts are secured in their proper situation, and not handled; a crust forms on the surface, and serves still further to protect and insure rest to the parts.

Dr. John T. Carpenter, of Pottsville, said:—I enjoyed the opportunity of practising antiseptic surgery on a somewhat extended scale, many years before the origination of the germ theory or of the use of carbolic acid. It was my fortune, in 1862, as Medical Director of the U. S. Army Hospitals in and around Cincinnati, to supervise the treatment of a large number of cases of Hospital Gangrene. Recognizing the extraordinary virulence of this septic

disease, and yet believing its constitutional symptoms to be exclusively the result of local infection, I directed the employment of an antiseptic local treatment, which met with most gratifying success. The hospital surgeons were directed to remove, as thoroughly as possible, the whole of the diseased tissues with the knife; to bathe the wound with *freshly generated* chlorine gas (used as chlorine water); to pack the then purified raw surfaces with lint saturated in creasote; and to trust to free ventilation, good food, and tonic treatment, for the rest. Of more than a hundred cases of hospital gangrene thus faithfully treated, I recall now but two which proved fatal, one from erosion of a large branch of the femoral artery, the other from thrombosis with enormous heart-clot. Here then was made a decided attempt, in treating a putrefactive disease: (1) to remove the poisoned tissues; (2) to disinfect those which could not be removed, and (3) to occupy the wound with a protective dressing as a means of preventing any re-inoculation by a poison which we all recognized as existing in the atmosphere of the wards. Here were recognized at that early date the principles of causation and of treatment which have only recently been thoroughly expanded and perfectly carried out. I may add that creasote was the only chemical agent known at that time which could substitute or replace our present carbolic acid, and which would produce results at all similar.

Dr. Frederic Hyde, of Cortland Village, N. Y., said:—In according value to any form of topical treatment, whether antiseptic or not, the true condition of the part, both at the time of and often anterior to the occurrence of the injury, should be taken into account. Whether the conditions existing before the wound or injury was received were strictly physiological, or more or less pathological, will materially influence the results of any and all forms of local treatment, and whatever importance and value may belong to one mode or another, we shall observe in the results that the rapidity or tardiness of repair, and the degree of recovery, will depend much upon the state of the patient at the time the injury was received.

Dr. R. F. Weir, of New York, said:—Perfect cleanliness is important in the treatment of wounds. By using cotton waste instead of sponges, by the employment of the douche for washing wounds, and by paying great attention to the cleansing of bedding, etc., we have been able to almost banish septicæmic diseases from the Roosevelt Hospital. We use both carbolic and salicylic acid, but not for the purpose of excluding germs from wounds.

On motion, the discussion of Dr. Hodgen's paper was adjourned, and the President, Professor Lister, was requested to address the Section the next day upon the subject of Antiseptic Surgery.

ANTISEPTIC SURGERY.

REPORT OF REMARKS MADE BEFORE THE SURGICAL SECTION, DURING THE ADJOURNED DISCUSSION ON DR. HODGEN'S PAPER.

BY

JOSEPH LISTER, F.R.S.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF EDINBURGH.

(PRESIDENT OF THE SECTION.)

Having been requested to address the Section on the subject of Antiseptic Surgery, I will reply to some of the objections which have from time to time been raised against this plan of treatment.

The first objection is, that it is "too much trouble." I grant that it is somewhat troublesome, and yet I believe that the trouble is more imaginary than real, and is one of the necessary results of a want of the proper apparatus and appliances, together with inexperience as to their use. There is always trouble with any operation until one has learned the minutiæ of the various steps. But even supposing that it does require a little more attention at the time of the operation, I think that when the infrequency of dressing, and the shortening of the period of cure, are taken into consideration, it will be seen that the labor performed is far less than when ordinary means are employed. Again, it is worth some trouble to be able to seal up an amputation, an exsection, or a large wound, with the absolute certainty that no evil effects will follow.

The second objection is, that "other modes of treatment give good results." I grant that they give good results, but not the best attainable. Without strict antiseptic treatment, it is impossible to freely lay open a knee-joint, with the certainty that no danger will follow; or to take out a wedge-shaped piece from either femur, as I have recently done, and yet to feel that such a produced compound fracture is perfectly safe, and without risk. And then we must consider the progress of the wound. The blood becomes organized under the dressings, and cicatrization occurs without one drop of pus, and almost without granulations, so that, when we take away the superficial blood-crust, a clean surface is found beneath. This I venture to say never could be done without antiseptic treatment. Again, to be able to open a chronic abscess of the spine, without fear of irritative fever, or pyæmia, requires the strictly antiseptic plan. And in acute abscess, it is pleasant to feel that after the procedure of opening and pressing out the accumulated material, not one drop more will form. Again, in the ligature of a large artery near a great branch, it is a great relief to know that rapid healing will occur, and that the danger of hemorrhage will be avoided. None of these things can be done without risk, unless putrefactive changes are strictly prevented.

I must object to the definition of Antiseptic Surgery, given by Prof. Hodgen, as that includes the disinfection of water-closets, etc. I pre-

fer to use the term "antiseptic system," and construe this as meaning "the dealing with surgical cases in such a way as to prevent the introduction of putrefactive influences into wounds."

Another objection which has been made, is that "putrefaction may be due to germs introduced from within;" but this is an objection easily met. Every simple fracture disproves it, for in every fracture we have a most serious wound, even although it is not visible to the eye—bones and soft tissues are all mutilated to a greater or less degree—and if partial destruction and mere feebleness of tissue would cause putrefaction, then we should have it occurring in every injury of this kind.

Another point raised by Dr. Hodgen, is that, when serious results occur after the opening of an abscess, they are caused not so much by putrefactive changes as by injury to the pyogenic membrane and consequent absorption. With all due deference, I would say that a pyogenic membrane is a much better absorbing surface than a mass of granulations. It is well known that large granulating surfaces, which are discharging so profusely as to taint with their horrible odor a whole hospital, yet are not sufficiently absorbent to injure the system to any perceptible degree.

Opening of such abscesses antiseptically, will certainly prevent putrefactive changes and a relaxed condition of the pyogenic membrane, and thus prevent constitutional disturbance. As to the cause of this disturbance, when the antiseptic system is not used, I would only say that in a chronic abscess the pyogenic membrane is not in the condition of a granulating surface. In acute abscesses it may be, but in chronic cavities we sometimes have no secretion of pus until after the abscess is opened. This is sometimes seen in cases of diseased bone, in which clear liquid is all that can be drawn off, and pus is not secreted until subsequently. In proportion to the chronicity of an abscess does its pyogenic membrane partake of the characteristics, not of a granulating surface, but of cicatricial tissue with the epidermis stripped off, and in this latter state it is vastly more likely to absorb. The bad symptoms usually appear within the first few days, while the membrane is in this condition, and patients sometimes die within twenty-four hours after the opening of the abscess, in which time the membrane certainly cannot have assumed the condition of a granulating surface. Pus may not form until the third day, while the irritative fever is usually observed earlier than this. The danger at first is from this irritative fever; afterwards, when the pyogenic membrane is in the condition of an open sore, from hectic.

[Prof. Lister then gave a practical demonstration of the application of the antiseptic system upon the person of a patient, and spoke of the different forms of carbolic acid.]

At first I used the German creasote, which is very offensive from the krealic acid which it contains. I now used the purest acid I can procure, which is absolute phenol, and I have found that its solubility and want of offensiveness are in direct proportion to its purity. Calvert's carbolic acid requires twenty parts of water to dissolve it, this only sixteen. Another advantage is that a solution in which there are no undissolved particles is far less irritating than one in which the little portions of pure acid are brought into direct contact either with the wound or the surgeon's hand. Pure carbolic acid is used most satisfactorily in water, and for detergent purposes it has no equal. It is exceedingly penetrating, as evidenced by its action on India-rubber, and when used in the proportion of

1 to 20, will most effectually purify every portion of the epidermis, while instruments soaked in the same solution are rendered thoroughly antiseptic. For the purposes of atomization, its volatility is an advantage, and although I most heartily wish that I could dispense with the spray, yet I do not see how it can be accomplished. Thiersch, of Leipsic, substituted salicylic acid for a time, but he has now returned to carbolic acid.

[Prof. Lister then showed a Spray Producer, manufactured by J. Gardner, of Edinburgh, which, by a modification of the French plan of having one tube and wick within another, was so arranged that alcohol was volatilized, and then this vapor burned, thus securing a very large flame and insuring a rapid stream from the boiler.]

When the pressure is sufficiently great, the atomization will be so fine that there will be scarcely any perceptible wetting of the surgeon's linen, and when thus minutely divided the carbolic acid is much less irritating to the wound. The large size of the stream is also of great advantage in giving a larger area for work. The surgeon should always see the spray, and then he will be certain that it is in the right place. When assistants are scarce, the atomizer can be placed upon a table and made to play upon the part.

The skin being throughly cleansed, the instruments soaked, the hands washed, finger-nails brushed, and sponges prepared, the incision is commenced; and from this time until the completion of the dressing, if the surgeon's hands or an instrument are passed beyond the area of spray, they must not be again brought near the wound until they have been dipped in the antiseptic solution. It is the close attention to these minute details that renders this system so absolutely certain and safe in its results. Carbolized catgut ligatures are always used, both ends being cut-off. Before closing the wound, a purified Chassaignac's drainage-tube is introduced, if needed, when the dressing can be applied with the perfect assurance that, every organism having been thus far excluded, none can enter the wound, and healing without suppuration will occur.

The gauze employed is simply loose, open, cheap, cotton-cloth, impregnated with carbolic acid, one part; paraffine, five parts; and common resin, seven parts, thoroughly spread over the surface when hot, and put under heavy pressure in a stout wooden box. The paraffine prevents stickiness, and the resin makes an excellent vehicle. In dressing a fresh wound it is best to protect the raw edges by a small piece of thin oiled silk, covered with copal varnish, in order to prevent any injurious effect from the direct contact of the carbolic acid, and to allow the blood clot more easily to organize. If this is done, a wound need not be opened for a week, but it will otherwise require earlier dressing. The next substance to be applied is a layer of gauze, soaked in fresh carbolic solution, since the dry gauze might contain organisms from accumulated dust, and in its dry state not be able to destroy them. Over this is placed half a dozen thicknesses of the same material, loosely wrapped around, the spray meanwhile playing continuously upon the part. Then is applied a layer of Mackintosh cloth, and over all is wrapped a loose bandage made of the same carbolized gauze torn into strips. The wound may now be left with a feeling of absolute security, and without any anxiety, for a week, or until the discharge begins to soak through, when the outer dressings may be raised under the spray, and fresh ones applied. The deep dressings need not be disturbed for weeks, if necessary. For changing the dressings, in private practice, I carry a small atomizer which can be packed in a box in the pocket. In wounds too large to be covered by the spray

from this instrument, one side can be dressed at a time. One or two dressings are all that are usually required.

I have found resin a most excellent vehicle for the carbolic acid, as it holds the latter with extreme tenacity, while at the same time it has no affinity for the discharges, allowing them to pass through for a long time without extracting the virtues of the acid. I have found also that the energy of a drug depends not alone upon its quantity, but upon the affinity of its vehicle, so that 1 to 5 of resin is no more pungent than 1 to 20 of oil, or 1 to 100 of water.

It may be thought that all this caution in dressing is unnecessary and troublesome, and it would be so if one had to do all this and then failed to secure a good result, but when these minutiæ are heeded bad results will not occur; wounds will heal so rapidly and kindly that one will soon come to find that it is not the most but the least troublesome mode of dressing, when he takes the course of the case into account. Many doubtless fall short of these good results simply because they neglect the precautions mentioned, and then they blame the system for their failure.

I have been making strenuous efforts to improve the catgut ligature, and believe that I have at last obtained the desired result. Old ligature is far preferable to new, and yet the knots will sometimes loosen. I have seen a case of Cæsarean section progress admirably until the stitches in the uterus gave way, and then death speedily followed. The old ligature is harder and does not absorb as readily as the new, but I have found that gut which is reliable when tested with warm water, will yet loosen under the action of the liquor sanguinis. The ligature must not be made too hard, or it will be too stiff for tying, and will even act as a foreign body as much as silk does, and yet it must be so hard that after soaking in serum for weeks it will still hold firmly. I have tried many substances; chromic acid will harden the gut, but when the latter is soaked in serum it is as unsatisfactory as before. Glycerine gives a ligature which will knot well, but is still too hard. I have at last made a mixture of carbolic acid, glycerine, chromic acid, spirit of wine, and water, which I think will prove the very thing required. The ligature which I show has been soaked a month in serum, and yet the knots are perfectly firm.

The germ theory of putrefaction is the foundation of the whole system of antiseptic surgery, and, if this theory is a fact, it is a fact of facts that the antiseptic system means the exclusion of all putrefactive organisms.

Burdon Sanderson a few years ago established a fact when he showed that water developed bacteria. When Pasteur's solution, with sugar and ammoniacal solutions, was boiled and exposed to the air, various forms of fungi were found, but no bacteria; but if one drop of undistilled water was added then these latter appeared. Again, when a wineglass was filled with cooled Pasteur's solution, bacteria were found in the contents; but these were attributed not to air dust but to adhering water upon the glass. If it were true that water alone was the carrier of these germs, it would be of no use to employ the spray; it would only be necessary to cleanse the hands and instruments. Formerly, when I used the carbolized putty, I have seen a joint which had been laid open do admirably until the blood clot at the wound was pulled away, when upon the next day the whole articulation would be in a state of putrefaction. I should like to know how this could occur save from air dust.

[Prof. Lister then showed a glass stand, cup, and cover, which he had used for his experiments. The cast-iron box in which they were heated to 300° F., in order to destroy all living organisms, was fitted with a cover, in the groove in the lid of which was placed cotton, in order to filter the air which would otherwise pass uninterrupted through the crevice during the cooling process.]

If a liquid free from organisms is introduced into such a prepared glass, it will remain without fermentation until it dries up. This proves that if a liquid be freed from living organisms, putrefaction will not occur. The lid may be raised for a moment, and some of the liquid secured for experimentation, yet no dust will enter during the short space of time required for this manœuvre. If instead of Pasteur's solution we use boiled milk, and remove the cover for fifteen minutes, then bacteria will appear. Milk is more favorable for the development of different kinds of bacteria than Pasteur's solution. We may have these organisms without putrefactive changes, and I have found them in milk treated as above described for days without any smell or putrefaction; but if we let in air or water, at once the liquid will putrefy. This would indicate that there are bacteria of several kinds, just as there are great numbers of torulæ which cause alcoholic fermentation. Boiled milk is not prone to sour, but if we introduce one drop of sweet milk, we almost immediately find bacteria.

Again, suppose that we try how such organisms behave in boiled urine. It may be objected that the boiling will prevent decomposition of the urine, but it is possible to obtain pure urine which has never been exposed to the influences of the air, and in which there is therefore no need of boiling to destroy any germs, unless those germs existed in the bladder. It may be set down as a rule that living tissues prevent the development of bacteria in their immediate vicinity. This is instanced in the puncture of an œdematous limb, where the liquor sanguinis which does not ooze away never putrefies, while if it were situated in meshes of cotton instead of connective tissue it would certainly do so, showing that the living structures prevent this process. Again, take the instance of healing under a scab; here is an underlying layer of liquor sanguinis, yet fermentation never occurs. Hence we might infer that the mucous membrane of the urethra would also exercise a forbidding effect upon the development of these germs, since, although the acts of micturition are infrequent, no organisms are ever found beyond the meatus, even when the glans and prepuce are abundantly supplied with them.

For experimentation, let the penis be thoroughly washed with a solution of carbolic acid, 1 to 40, which will produce no irritation; then, taking a flask which has been removed from the "heating box" before described, gently lift the cover, and let the patient micturate into the flask. One will then have pure, uncontaminated, unboiled urine, which will keep for a year, even although it contains vesical mucus. When it is wished to obtain some of the contents of this flask, it is only necessary to remove the cap, slip over the mouth one-half of a rubber ball, which has been steeped in carbolic acid, and through a hole in this any amount can be poured, the little drop remaining at the orifice acting as a valve.

Into one of these glasses of unboiled, pure urine, put one drop of boiled milk. The first day, nothing; the second, a dimness and milkiness; and now, if we look, we will find long, spiral forms of bacteria. Inoculate a second glass of urine with one drop of this liquid; and now the bacteria, having become accustomed to the liquid, will cause it to become filled with germs within a few hours. Transfer a drop from the second

glass into Pasteur's solution; again we have bacteria, but of different forms. The former were motionless; these are quite active. Now inoculate a glass of boiled milk, and large, moving germs are soon seen. One drop of this last will produce lactic acid fermentation almost immediately. If we believe that torulæ are the cause of alcoholic fermentation, *à fortiori* we must believe that the bacteria lactis are the cause of lactic acid fermentation.

In regard to the inferences to be drawn from these experiments in regard to the healing of wounds, I would ask why the effused lymph, in the operation for harelip, does not putrefy? I believe that the explanation is to be found in the fact that this lymph lies between two healthy living surfaces, which prevent the development of organisms just as does the urethral mucous membrane. I believe that we should even go further, and say that blood-clot should also be regarded as tissue. I made an experiment several years ago, which consisted in laying bare the jugular vein of an ox, just struck down, applying two ligatures, and cutting away the vein beyond each, thus obtaining a receptacle of living tissue containing blood. This vein could be kept for hours without any change taking place in its contents. I then drew out the blood into a flask, and covered it with gutta-percha to prevent evaporation and dust; for twenty-four hours the blood still remained fluid, save where it was in contact with the glass, but the instant that the glass was stirred, coagulation took place.

The formation of clots in aneurismal sacs may be explained by this experiment; as long as the wall remains smooth and uninjured, clotting does not occur; but when the sac is injured, or free circulation interfered with, then coagulation takes place. If the blood-clot in wounds does not receive injury, it will organize, and should be accounted as tissue. In this blood-clot are many consituents—fibrin, white corpuscles, etc. These leucocytes act just as the connective-tissue corpuscles, and prevent fermentation, and the explanation of the organization of blood-clots, when not disturbed, can thus be explained. Putrefactive changes may be introduced into the clot, and yet putrefaction not occur—a circumstance which can be best accounted for by the fact that the clot acts as a living tissue, and thus prevents putrefaction, just as does the urethral mucous membrane before mentioned. There are undoubtedly often deep blood-clots in the tissues when acupressure is used after amputations; and yet these fail to putrefy, but become organized. This may occur under any form of treatment, but by employing the antiseptic system such a result is rendered exceedingly probable.

As regards the question of constitutional treatment which has been raised, I would say that, with strict antiseptic precautions, the wound is placed in a condition similar to that of a simple fracture, in which the injured parts are free from the dangers of atmospheric exposure, and the surgeon has far less need to attend so closely to the patient's constitutional condition, as the cases will almost always progress favorably.

The statement that cell-forms have been found beneath antiseptic dressings, must be received with caution. I have recently met a gentleman who was with Raneke, in Halle, when he found, as he supposed, these organisms beneath antiseptic coverings; and when this gentleman pointed out to me the bacteria which he called putrefactive, I at once recognized them as of the non-putrefactive variety; and the gentleman was forced to admit that they differed from those found in decomposing masses.

As regards bacteria found in abscesses when the skin is not broken, and in which Dr. Hodgen stated that the forms came from within, I think the instances are very rare, although I acknowledge that such cases do occur. Again, it does not follow that every foul-smelling abscess is putrefactive. In ischio-rectal abscesses there is usually a stinking odor, even although no communication has been established with the bowel. My treatment for this class of cases has been not to poultice them, for that would surely make a true fistula, but, after thoroughly disinfecting the skin, to lay them freely open under the spray. I then cover them with lint soaked in carbolized oil, and over the mass place a T-bandage, which can be drawn aside at each act of defecation. I never inject them, nor use a drainage tube. Under this treatment they soon heal without either suppuration or odor; and I have never failed to secure this result save in one case, in which the house-surgeon, on the first day, failed to change the dressings under the spray.

In regard to salicylic acid, I think its action is chemical, and that it is especially useful in destroying those odors which are not the result of putrefactive change. That it has this chemical property is proved by the fact that, when mixed with amygdaline and emulsine, it prevents the formation of hydrocyanic acid. Mixed with mustard, also, it prevents the evolution of the volatile oil. I have thought that the action of salicylic acid is very similar upon living tissues. Other classes of cases for which this agent is especially suitable, are compound fractures, which do better if kept closed for weeks, and yet are liable to become offensive before the expiration of that time, and chronic abscesses connected with diseased vertebræ, when the skin is excoriated and ulcerated. In such cases I simply smear the under surface of the carbolized gauze with the powder of salicylic acid, and then have allowed a single covering to remain for six weeks without either odor or irritation.

Discussion on Mr. Lister's Address.

Upon the conclusion of Prof. Lister's remarks, Dr. W. H. Van Buren, of New York, said:—I would ask how far the antiseptic treatment is applicable to a certain class of operations, as, for instance, those for the relief of strangulated hernia; and how far it is safe to throw the carbolized spray upon the peritoneum in ovariotomy and laparotomy? Absorption has occurred in such cases, as evidenced by the production of hæmaturia, and other symptoms of carbolic acid poisoning.

Mr. Lister said:—Upon this point I can speak from experience, as I have repeatedly operated for strangulated hernia under the spray, and, in one case of abdominal wound, a cloth soaked in the carbolic solution lay upon the exposed intestines for several hours without producing any irritation. As for ovariotomy, I am informed that Mr. Keith now uses the spray in all his operations, and also that Nüssbaum attributes his great success in this class of cases to the use of the antiseptic system. I myself think that the danger to be apprehended is not so much from peritonitis as from the toxic effects of the acid. In one case, in which a large ovarian tumor had been removed and hemorrhage occurred, I did not open the wound, but simply applied a large carbolized sponge, with pressure, and although a large amount of clotted blood remained in the peritoneal cavity, yet no inflammation resulted. I have seen a few cases of danger from the toxic effects of carbolic acid, the symptoms being weakness, failure of appetite, sometimes vomiting, and the urine very much darkened. These effects have seldom occurred since I have ceased the

use of the antiseptic putty, and I believe that they will only be found where there is a peculiar idiosyncrasy.

Salicylic acid I consider inferior to carbolic acid as a detergent, yet, in those cases in which a deep dressing is to be left on for weeks, and in which the odor is apt to become very offensive, I have used it with great advantage. This odor is particularly disagreeable in dressings applied to the feet, axilla, or perineum, and is not due to putrefaction or to the presence of organisms.

Dr. T. E. SATTERTHWAITE, of New York, said:—The vegetable germ theory seems to be regarded by some as an essential foundation for the antiseptic system of surgery.

The hour being late, I merely desire to point out a few facts which, in my opinion, militate against the theory, as far as it claims that a certain class of minute living organisms of a vegetable character is essential to disease-processes. Pasteur has, of late, considerably modified his ideas, so far as to acknowledge that alcoholic fermentation may be initiated without the presence of certain minute living vegetable organisms, in other words, torulæ or allied forms, whatever their name. A statement to this effect was made at the recent discussion on the Germ Theory in London. Le Chartier and Bellamy have observed that, in some modified forms of alcoholic fermentation, such minute organisms may at first be absent, though later they make their appearance. Again, Hiller has inoculated eggs with bacteria, and no putrefaction has ensued. Some French observers also have found no organisms present in putrefaction.

These facts are stated to show merely that it is questionable whether alcoholic fermentation and putrefaction are due solely to certain minute living vegetable organisms, to the growth and multiplication of which these processes are due.

The early views of Pasteur have met with opposition, notably from Liebig, Stahl, and others of the German school, and views of a somewhat similar nature are still maintained now by those who oppose the "germ theory." As for the changes which it has been stated take place in one and the same bacterial body, under differing circumstances, I think that this is an important and interesting fact, and one that has not as yet received sufficient recognition. But it is an argument that is exceedingly valuable to those who do not believe in the vegetable germ theory. It helps to explain a fact that has led to a great deal of confusion, viz., that the different organisms alleged to be found in different diseases may owe their differing form not to the disease, necessarily, but rather to the peculiar menstruum in which they happen to be.

With regard to the experiment recited by Mr. Lister, in which urine was passed into a glass vessel that contained air, but no floating particles, where the fluid continued to resist ammoniacal decomposition until, the air being admitted, it was seen to contain particles, I would say that the presence of these particles does not necessarily indicate that they are bacteria; in fact, the experiments of Blackley, in England, and of Wyman and others, have shown that the air contains numerous particles beside bacteria, such as the pollen of grasses, epithelial scales, and what is known as granular matter, whatever that may happen to be in any given case; and we have a right, in view of certain other experiments, such as the production of putrefaction without bacteria, to believe that some of these particles—not bacteria—may have occasioned the change.

The same statement applies to Prof. Tyndall's experiments, in which he passed the beam of the electric light through a box fitted with windows, where the box contained matter easily susceptible of putrefactive change. When the electric beam showed that the inclosed air contained floating motes, then the fluids soon commenced to putrefy, but when the beam showed that the particles were no longer in the air, the tubes might be introduced and exposed to the air, and yet would remain unchanged indefinitely. Now it is implied by Prof. Tyndall that the presence of particles is synonymous with the presence

of bacteria, which is certainly an assumption, as the electric beam does not show that these particles are bacteria in distinction from other particles.

Experiments with vacuum tubes in relation to putrid matters, if performed with delicacy, tend to show that the fluid of such infusions, although virulent in so far as inoculation is concerned, may still remain clear or transparent for an indefinite time, without the formation of bacteria.

In some experiments made with salicylic acid and putrid matter intimately mixed, infection took place in animals I inoculated, when the quantity of salicylic acid was sufficient to prevent the development of bacteria in organic infusions. These are simply a few of the points maintained by those who oppose the vegetable germ theory as generally accepted. In my paper read in the Section on Sanitary Science, these and other facts are stated at more length.

Mr. LISTER said:—I am of the opinion that Pasteur has not materially modified his views. The penicilium glaucum, without air, produces a degree of alcoholic fermentation; there are also certain forms, which when grown under water have thick filaments, with loose joints, and which closely resemble torulæ; but, if in oxygen, the growth is much more rapid, and the similitude is less marked. Pasteur made an experiment with grapes kept in an atmosphere of carbonic acid, and although they showed evident signs of fermentation, yet Pasteur attributed this process to the natural change in the vegetable cells of the fruit itself, and not to organisms.

I have made numerous experiments to determine the question as to whether the cause of fermentation is a chemical or a vital one; also whether this is in solution in water, or in suspension. I can hardly believe that living things are soluble, and yet if they are only in suspension, by taking minute enough drops, we ought to avoid them. I have tried as small a quantity as $\frac{1}{200}$ of a drop of putrefying liquid, introduced by means of a syringe into different solutions, and have found that no matter how small the quantity used, yet under favoring circumstances, bacteria are developed. I would mention as a point worthy of note, that I have discovered that bacteria are killed by the reduction of temperature to a degree still considerably above the freezing point.

Dr. SATTERTHWAITE said:—In regard to the modification of Pasteur's views which I stated had taken place, the instances referred to by Prof. Lister illustrate the point which I am desirous of making.

In certain of these instances, as in the well-known experiment where grapes were suspended in an atmosphere of carbonic acid, Pasteur admits[1] that fermentation took place without the intervention of certain minute organisms, by which is doubtless meant the yeast plant or other allied organisms. The ferment was, in this case, Pasteur said, the tissue elements of the fruit, the vegetable cells, rather than the minute organisms known as fungi, torulæ, etc. I am aware that Pasteur claims that this admission does not necessarily affect his doctrine, but I must still maintain that Pasteur's view, as generally understood, is considerably modified, to use no stronger expression. The ferment is in this case stated to be the substance of the fruit, rather than a minute microscopic organism ranked among the cryptogams. This is the only point I am desirous of making in this matter, and the object of introducing it is not so much because fermentation and putrefaction have to do with the discussion, as because the connection between minute living organisms and these processes is brought forward as good *à priori* evidence of a similar relation existing between other minute organisms, such as bacteria and disease-processes.

In reference to Liebig and others of the German school who have opposed Pasteur, I did not allude to them as expressing distinct statements as to the nature of the fermentative agent, for these views varied as the discussion on

[1] Bull. de l'Acad. de Médecine, Mar. 2, 1875, No. 9, p. 255; Lancet, April 10, 1875, p. 508.

these topics went on, but rather as showing that there have been and still are[1] those who believe that these changes are not dependent on the growth and multiplication of such living organisms as have been described.

In reference to the nature of disease-poisons, it does not necessarily follow that because they may not be bacteria, they may not be molecular; indeed, it is my present conviction that this is the case in a certain number of instances, as filtration experiments appear to show. The most virulent fluids with which I have experimented have never produced lesions when they have been passed through porous clay.

Mr. Lister said:—Pasteur has shown that if the grape is bruised, and then placed in the atmosphere of carbolic acid, fermentation no longer takes place; implying that only living tissues undergo this change. I have tried the experiment of passing solutions through pores so fine as to arrest bacteria, but I have found that albumen is also stopped, and it may be that chemical substances in solution are also prevented from passing; consequently the experiment proves nothing save that the cause of fermentation has been prevented from passing.

THE TREATMENT OF ANEURISM.

BY

W. H. VAN BUREN, A.M., M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

In seeking for information concerning the medical and surgical treatment of aneurism, we find by far the most ample experience in the records of English surgery. Breschet, in his well-known memoir on aneurism, published in Paris in 1832, frankly admits that the pathology of this disease had received more attention in England than in France, because of its greater frequency in that country.[1] The greater frequency of aneurism in the British Islands than elsewhere still exists; and, unless we accept the suggestion that it is the result of the more general use of beer and spirits in those countries, I must follow Breschet in ignoring its cause. Although our own country has been singularly prominent in the boldness and success of operations upon the great arteries for aneurism, yet the disease is not so frequent here as in England, and at the same time spirit-drinking is very common. On the continent of Europe, where the consumption of spirits is less general, aneurism is comparatively rare. In connection with the etiology of the disease it is to be remarked that the weight of opinion in favor of syphilis as a cause of aneurism is noticeably less than formerly.

In the very able lectures on the treatment of aneurism delivered in 1872, 1873, and 1874, by Mr. Timothy Holmes, as Professor of Surgical Pathology in the Royal College of Surgeons of London, he states that, in collecting his materials, he addressed letters to more than thirty hospital surgeons throughout Great Britain and Ireland, and that he received notes of no less than three hundred and thirty-seven cases of aneurism, in reply, covering ten years of practice. Mr. Holmes complains, moreover, that the pathological museums of London alone are so overstocked with material that it is difficult to master their contents, whilst the bulk of published matter outruns the best efforts of any one inquirer to keep up with it. Such recent and ample supply of material bearing on our subject leaves little scope for further research, and the evident ability shown in its collation and digestion gives these lectures great value. Since Guthrie lectured on this subject from the same chair more than forty years ago, we have had nothing more judicial and authoritative. I shall, of necessity, draw largely from them in this report.[2]

The purely medical treatment of aneurism, more especially of internal aneurism, has risen into greater importance within the past ten years. Mr. Jolliffe Tufnell, of Dublin, has fairly and ably demonstrated the posi-

[1] Mémoires de l'Académie de Médecine de Paris, t. iii.

[2] It is to be regretted that Mr. Holmes's eighteen lectures "on the medical and surgical treatment of aneurism in its various forms" are only accessible in the pages of the journals in which they were reported at the time, without any copies of the drawings, or tables, or pathological preparations by which they were illustrated. They are too valuable to the profession not to be reproduced in a more permanent form.

tive value of absolute repose in the horizontal position, conjoined with a greatly restricted diet, omitting entirely the frequent bleedings which had brought the so-called treatment of Valsalva into disfavor. Mr. Tufnell's successful results certainly justify the systematic enforcement of his method, especially in cases of thoracic and abdominal aneurism, which we are too much in the habit of regarding as incurable. "The method I advocate," says Mr. Tufnell, "is the imitation of nature's cure; the production artificially of that consolidation which in isolated cases has from time to time occurred spontaneously." The recumbent position is the secret of cure, *but it must be steadily maintained.* It places the same check upon the circulation in internal aneurism which in external cases is produced by mechanical appliances. Three months of horizontal position, with eight ounces of solid food and six ounces of fluid as daily allowance, were the measures with which he cured Doyle, a hackney coachman of thirty-five, with an abdominal aneurism as large as an orange.[1] Tufnell's method is legitimately derived from the principle so ably illustrated by the Irish surgeons when they established the value of compression as a remedy, the principle originally demonstrated by Hunter, that to produce coagulation in an aneurismal sac it is only necessary to slow its current of blood, not to arrest it entirely; and, in the judgment of the writer it is destined hereafter to play a prominent part in the therapeutics of aneurism.

The aid of drugs has been also invoked in the medical treatment of aneurism for the purpose of slowing the action of the heart and favoring coagulation; digitaline and ergotine have been used by Albertini; and Langenbeck has made trial of ergot in subcutaneous injection. Acetate of lead has also been used internally. I have met with little evidence in their favor. A case of orbital aneurism is reported by Dr. Holmes, of Chicago, which got well after six weeks' use of tincture of veratrum viride in doses of five minims, with a fluidrachm of extract of ergot, suggested by the late Professor Brainard.[2]

In a recently published work Dr. Balfour brings forward further evidences of the value of potassium iodide in causing solidification of internal aneurism.[3] This remedy has been tested by the profession, and there are favorable reports of it.[4] In many instances, however, the recumbent position and restricted diet have been employed at the same time with the iodide. In aneurism in a syphilitic subject its use would be indicated. Pretty certainly the iodide in such a case would increase the number of the red globules of the blood, as Keyes has observed to be the case under the use of small doses of mercury, and, possibly, also, its fibrinating power.[5] Until we gain more accurate knowledge of the causes

[1] The Successful Treatment of Internal Aneurism by Consolidation of the Contents of the Sac. By Jolliffe Tufnell, F.R.C.S.I., etc., President of the Royal College of Surgeons of Ireland, etc.; 2d edition, London, 1875.

which modify the quality or quantity of its fibrin, the mode of action of drugs in favoring coagulation of the blood must remain obscure.

The *ligature*, as applied by Hunter, maintains its character in a general way as the most prompt and certain of the surgical remedies for aneurism, and, when not employed in the first instance, it is always held in reserve as a final resort in all cases to which it is applicable; but safer methods of cure are constantly being sought for in order to escape the dangers which are still inseparable from the use of the ligature, viz., hemorrhage, gangrene, and inflammation of the aneurismal sac.

The ligature of carbolized catgut prepared by Professor Lister's method offers the best promise, at this time, as a preventive of secondary hemorrhage. Bickersteth, of Liverpool,[1] Pemberton, of Birmingham, Heath, Maunder and Holmes, of London, besides Professor Lister himself, certain of his colleagues of the Royal Infirmary of Edinburgh, and others, have recorded evidence that the carbolized catgut ligature is competent to constrict an artery for a sufficient time to bring about the consolidation of an aneurism without causing ulceration of its coats. After this duty has been accomplished the substance of the ligature then softens into a mass which is, as it seems, capable of serving as a nidus for cell-growth, and, having excited no suppuration whatever, the catgut becomes finally identified with the surrounding tissues.[2] Thus, after such a ligature has been applied, both of its ends may be cut off and the wound closed as for quick union. This latter result is more likely to be attained, according to Professor Lister, when the operation is done under carbolized spray, and the wound dressed according to the antiseptic method. The Edinburgh surgeon expresses his readiness to ligate the innominate artery by this method, believing confidently that the vessel will be obliterated with greatly diminished risk of suppuration and ulceration, and with increased chances of rapid consolidation of the wound.[3] A double surety would be thus obtained against secondary hemorrhage.

It is proper to state, however, that some instances have been recorded

[1] An Introductory Address on Recent Progress in Surgery, delivered at the Liverpool Medical Institution, Liverpool, 1871, p. 20.

[2] Observations on the Ligature of Arteries on the Antiseptic System, by Joseph Lister, F.R.S., etc., Lancet, April 3, 1869, p. 451. More recently, Professor Lister's statements have been confirmed by Mr. Fleming, Lecturer on Physiology in the Glasgow School of Medicine, in a very conclusive series of experiments on dogs and rabbits, reported in the London Lancet, May 27, 1876, p. 771. Mr. F. says: "The results of these experiments show that a gradual softening takes place from without in, the catgut breaking down and becoming infiltrated with cells, probably leucocytes. This part of the process takes from five days to about twenty, varying with the specimen of catgut, the tissue amongst which it is situated, and the age and vitality of the animal. Next the pultaceous mass into which it has been converted, begins to metamorphose, and is soon permeated with blood channels, and ultimately may be described as a cast of the catgut, in a kind of granulation tissue freely supplied with bloodvessels, which in many of my sections are very fully injected.

"If, then, we admit these conclusions, we can easily account for the different results obtained by the use of catgut in different hands. We see that it is in reality merely a temporary ligature, because when in the softened stage we cannot consider it to have any constricting effect.

"Whether, then, this temporary condition lasts long enough to produce embolic occlusion of the vessels, depends upon the sample of catgut and the vitality of the patient.

"In conclusion, my experiments seem to demonstrate that an aseptic, dead, foreign, animal body may under appropriate conditions become, by a process of softening, absorption, and re-deposition, changed into or replaced by a living, vascular, and comparatively highly organized, animal structure."

[3] Holmes's Lectures on the Treatment of Aneurism, ut supra, Lancet, June, 1872.

in which the catgut ligature has become prematurely soft, and pulsation has returned in the aneurism ; and in which, when the wound has not united, secondary hemorrhage has occurred.[1] The answer has been made that in these cases of failure the catgut may not have been well prepared, and that the necessary details of the antiseptic method were possibly neglected.[2]

Meanwhile, those who, like Mr. Maunder, lack confidence in the catgut ligature, have reverted to the use of carbolized silk, which was employed by Professor Lister before he adopted the catgut; and it has been found in several reported cases to answer the same purpose. There is no danger that the carbolized silk ligature will give way, but Lister had reason to suspect that it might provoke suppuration, and therefore preferred the catgut.[3]

The problem is to discover a mode of preparing catgut ligatures so that they shall possess first the right amount of strength and durability when exposed to soakage in the tissues, and at the same time that their very desirable quality of disappearing by blending with the tissues shall not be impaired. Professor Lister has just announced to us that he has reason to believe that he has succeeded in solving this problem, which has cost him so much labor. By this event surgery will have secured a great triumph over the danger of secondary hemorrhage after ligature of the great arteries for aneurism.

The employment of pressure upon an artery previous to its ligature has been heretofore regarded as a means of averting the danger of gangrene, which, according to Norris, causes 12.2 per cent. of all the deaths after ligature of large arteries for aneurism.[4] As early as 1820, Todd, of Dublin, had practised compression as a preparatory course prior to operation "in order that mortification of the limb might be prevented by allowing some progress to be made in establishing the collateral circu-

[1] My late colleague, Dr. Krackowizer, used a carbolized catgut ligature upon the primitive iliac artery for aneurism at the German Hospital, New York, and pulsation returned in the tumor within twenty-four hours, rendering it necessary to reopen the wound and apply another ligature. Similar cases are recorded by Dr. E. Watson, of Glasgow, in the Glasgow Med. Journ., May, 1870, p. 340 ; by Professor Spence, of Edinburgh, in the Lancet, June 5, 1869 ; by Mr. Holden, in St. Bartholomew's Hosp. Reports, vol. viii. p. 187 ; by Mr. H. L. Browne, Lancet, May 6, 1876 ; and by Mr. Maunder, in Surgery of the Arteries, London, 1875, p. 147, where the results of ten cases of "antiseptic" ligature are detailed, some of which are favorable, and others the reverse.

[2] It is only fair and just to Professor Lister that when the remedy he has proposed is under judgment, the conditions under which he employs it, and on the strength of which he recommends it, should be strictly complied with.

[3] Careful microscopic examination of the tissues around a loop of prepared silk which had successfully obliterated an artery, after rapid healing of the wound, in one of the lower animals, has shown as a rule the persistent presence of portions of the substance of the silk, which have been found in several instances surrounded by granulation tissue in process of organization along with some pus corpuscles, proving that silk does not become entirely blended with the tissues, and does not so readily lose its identity as the properly prepared catgut. Lister, ut supra.

In a recently published clinical lecture at the Royal Infirmary, Glasgow, Dr. Eben Watson describes a patient in whom he had tied both external iliacs for inguinal aneurism at an interval of nine months. Both operations were done under carbolic spray, carbolized silk ligatures applied, and then cut off. The wounds healed well, and the ligatures were never heard of. Dr. W. gives evidence for his belief that they became encapsulated. He prefers them to catgut, which, for reasons derived from his own experience, he considers less safe than silk. Lancet, Aug. 12, 1876, p. 213.

[4] Contributions to Practical Surgery, Philadelphia, 1873. In one hundred and eighty-eight cases of ligature of large arteries for aneurism, gangrene occurred in thirty-one, and was the cause of death in twenty-three.

lation."[1] This idea has been effectively disputed recently, by Mr. Holmes, who, controverting certain conclusions arrived at by Mr. Jonathan Hutchinson, asserts that the larger experience contained in his (Holmes's) collected table of hospital cases leads to precisely the opposite conclusion, viz., *that the mortality from ligature, after compression has failed, is* 10 *per cent. greater than when the Hunterian operation has been performed at once.*[2]

Mr. Clement Walter tied the external iliac, at St. George's Hospital, for inguinal aneurism, after six weeks' trial of pressure, both distal and proximal, as well as flexion, without avail, and the patient died in four days with incipient gangrene.[3] It is well known, also, that pressure, especially if intermittent, or irregularly applied, is liable to provoke inflammation of the sac; and that it is possible, in rare instances, for pressure itself, alone, to occasion gangrene, as in a case recently reported by Dr. Oscar H. Allis, of Philadelphia.[4] These facts should teach us, when it is decided to try compression, to use all possible means to command prompt success, and, these failing, *not to prolong unavailing efforts.*

The prestige acquired for the Hunterian operation by the brilliant successes of Astley Cooper, Abernethy, Travers, Mott, and others, caused the ligature to be regarded, during the first half of this century, as the remedy above all others for all forms of aneurism, wherever its application was possible; and it continued to be so regarded, in spite of its really high mortality, until the feasibility of a safer cure by compression was established by the Dublin surgeons. After it became an established fact that the disease was safely curable by compression, numerous other devices were proposed to attain the same end to the exclusion of the ligature, and of compression also; some of greater, others of less promise, but mainly of a bloodless and safer character. These methods, after a few remarks on compression, I propose to enumerate.

Meanwhile, it seems to me profitable to ask ourselves how far English and American surgeons may have carried a partiality for Hunter's operation to excess, and tied arteries for aneurism in cases in which other methods might have offered a better chance for life? That this has been the case in some degree we have the authority of Syme, of Edinburgh, undoubtedly one of the greatest operators of his day. Towards the close of his life, this surgeon formally raised the question as to the applicability of Hunter's operation to axillary and iliac aneurisms, after having advocated it, as he states, for thirty years. After a series of operations upon the greater arteries, unequalled in brilliancy and success, he felt himself justified in asserting that "aneurisms of the popliteal, femoral, and carotid arteries alone are proper subjects for ligature by the Hunterian method," and that all other aneurisms are more safely treated

[1] Practical Remarks on the Treatment of Aneurism by Compression, with plates of instruments, etc., by Jolliffe Tufnell, M.R.I.A., etc. etc., Dublin, 1851, p. 24. Tufnell here quotes Todd, who adds, "at the same time *not altogether without hope* that by diminishing the current of blood in the trunk of the artery so as to favor coagulation of the blood in the sac, a cure without operation might be effected." This is interesting as showing that the idea of cure by compression was still fairly in view at this early period.

[2] Lecture iv., part i., 3d series, Lancet, July, 1874. The probability of this conclusion had been already demonstrated by Dr. J. Ashhurst, Jr., in his System of Surgery, Phila., 1871, p. 543.

[3] St. George's Hospital Reports, vol. vi., 1871–72.

[4] In a robust colored man of 50, with a recent popliteal aneurism, a cure was effected on a second attempt at compression in thirteen hours. Gangrene appeared in the foot and leg on the next day, and the patient died in eight days. Dr. Allis states that he has found one other case of gangrene after pressure. Trans. Path. Soc., Phila., 1874, vol. iv. p. 117.

by the old operation of laying open the sac.[1] After careful study of his very interesting cases, it is difficult to refuse a large share of assent to Syme's conclusions. Even if we cannot admit his premises, which have been shown to be untenable by Holmes and Henry Lee, and refuse to return formally to the "old operation," preferring to trust to the medical treatment of Tufnell, or to the promises held out by galvano-puncture, coagulating injections, the manipulation of Fergusson, distal ligature in one of its new applications, or even to some form of compression—which Syme, through what Holmes calls a "strange prejudice," so singularly undervalued—nevertheless, the terrible mortality of the Hunterian operation in subclavian, axillary, and iliac aneurisms demonstrates clearly that the Edinburgh surgeon was right in raising the question of its applicability to these cases. "The Hunterian operation on the inominata," says Holmes, "and upon the first part of the subclavian, gives twenty-eight cases, in only one of which did the patient survive, and then after repeated attacks of hemorrhage—a ghastly record of death and blood."[2] The ligature of the second and third parts of the subclavian for aneurism is also very unpromising; Mr. Poland gives us twenty-one cases, of which only nine recovered.[3] In consequence of the pushing up of the clavicle by the growing tumor, ligature of the subclavian in its third portion for aneurism is often difficult, sometimes impossible, and always dangerous. Dupuytren abandoned it on one occasion, after persevering for an hour and a half, asserting that it was the most difficult operation he had ever undertaken; and Liston punctured the aneurismal sac in carrying his ligature around the vessel, and lost his patient.[4] On the other hand, in two cases of rapidly advancing axillary aneurism, Syme limited himself to dividing the tissues at the root of the neck so as to permit a finger to be introduced to compress the artery against the first rib, and then he laid open the tumor in the axilla and tied the vessel as it entered and again as it left the sac, and in both instances saved his patient. In two cases of axillary aneurism of a still more desperate character, he succeeded in saving the patients by amputation at the shoulder-joint after the ligature had failed; and Mr. Spence adopted the same mode of procedure, at least with temporary advantage, in a case of subclavian aneurism.[5]

Now, granting that Syme has demonstrated that laying open an aneurism is a safer and more certain mode of cure than the Hunterian ligature in these localites and others similarly situated, where pressure can be momentarily effected between the tumor and the heart, does not this success also prove that it is feasible to attempt a cure, perhaps at an earlier period, by galvano-puncture, or coagulating injections?—for it is in cases in which the circulation can be thus suspended that these novel and ingenious remedies offer the best prospect of successful application.

[2] This includes thirteen cases of ligation of the innominata, and fifteen of the subclavian. Holmes, ut supra, Lect. iv., part ii., 1st series, 1872.

[3] Statistics of Subclavian Aneurism, by Alfred Poland, Guy's Hospital Reports, vols. xv., xvi., xvii.

[4] Surgeon Otis, of the U. S. Army (in Medical and Surgical History of the Rebellion), gives 76 per cent. of deaths for ligature of the subclavian outside of the scaleni, mainly for hemorrhage or traumatic aneurisms after gunshot wounds, however. In my table of eighty-six cases of the same operation for all causes, the deaths were nearly 40 per cent. Contributions to Practical Surgery, Phila. 1865, p. 194.

[5] See Mr. Poland's paper in Med.-Chir. Trans., vol. lii. p. 277.

In thirty-two cases of ligature of the primitive iliac, tabulated by Dr. Stephen Smith, of New York, the operation was done for aneurism in fifteen, in which ten died, and one only, Mott's patient,[1] was permanently cured.[2]

Whatever value, therefore, may be ultimately assigned to the operation of Hunter elsewhere in the arterial system, it seems clear that, in these localities at least, it has proved neither safe nor reliable, and cannot be so regarded in future.

For gluteal aneurism, the Hunterian operation is equally unpromising. Holmes, who studied this subject thoroughly two years ago, succeeded in collecting but twelve cases in which the disease was considered spontaneous, and for which the internal or common iliac had been ligated; of these five, or nearly half, died.[3] On the other hand, there were twenty-one cases in which the affection was pretty certainly traumatic; in two of these the Hunterian operation was done—one of them the case of Dr. Bigelow, of Boston—and both ended fatally. To these I can add an unpublished case I witnessed in the Bellevue Hospital, New York, some years ago, in which ligature of the internal iliac was undertaken, but the patient died within a few days, as was supposed, from wound of the iliac vein. There are several other cases on record in which the same cause of death is noted, showing the difficulties which attend the ligature of this vessel.

In summing up his conclusions concerning gluteal aneurism, Holmes hardly shows his usual surgical acumen. He says: "The old operation by laying open the sac and tying the vessel, is a desperate business, and in spite of the really considerable amount of success which has attended it, no prudent surgeon could contemplate it without repugnance." Now, if the success of the old operation in gluteal aneurism has been "really considerable," as could be readily shown if time permitted, is not this conclusion rather sentimental than surgical? The affection is undoubtedly, in the great majority of cases, traumatic in its origin, and the treatment demanded is that of a wounded artery, whenever practicable. Syme succeeded by laying open the sac, following the lead of John Bell in his famous case of the leech catcher. Mr. Bickersteth, of Liverpool, and others, have been also successful in a similar mode of procedure. The source of fatal delay in quite a number of cases has been the fear of uncontrollable hemorrhage, and lack of power to command it. This risk, in the hands of a less confident and skilful operator than Syme, is a great drawback, and it is certainly very desirable to find some safe mode of commanding the circulation in this locality. Lister's aortic clamp, as used by Syme in the case in which he successfully attacked an iliac aneurism by the old operation, is not free from danger of crushing the intestines and causing congestion of the kidneys, as proved by Mr. Bryant's fatal case at St. Bartholomew's.[4]

I have a suggestion to offer which seems to me feasible and effective,

[1] Phila. Journ. Med. and Phys. Sciences, vol. xiv. p. 176.
[2] Amer. Journ. Med. Sciences, July, 1860.
[3] Lectures, ut supra, June, 1874.
[4] This was an attempt to cure an aneurism of the aorta very near the diaphragm by means of distal pressure. Holmes's Lectures, ut supra.

Mr. Geo. Pollock, in trying the rapid pressure treatment with Lister's compressor upon the aorta with chloroform for two hours and ten minutes, and again with ether for an hour and a quarter, was obliged to desist on account of faintness on each occasion. The attempt was also followed by hæmaturia which lasted for several days. He did not succeed. Trans. Clin. Soc. London, vol. vii. 1874.

and which I shall put in practice if I encounter one of these rare cases. In explorations of the rectum, after stretching the sphincter ani, where several fingers or the whole hand, after the suggestion of Simon, of Heidelberg, have been introduced into the bowel, I have been struck with the facility with which the great arteries of the pelvic cavity could be felt by the fingers, and compressed against its bony walls; and I am confident that either the external or internal iliac or their common trunk could be thus easily commanded long enough to render it a safe operation to lay open a gluteal aneurism and secure the artery involved, if external to the pelvis. All that is necessary is a reliable assistant with a small hand, who is somewhat familiar with the manœuvre.[1]

If, possibly, a gluteal aneurism should take its origin within the pelvis, emerging through the sciatic opening, this fact might be also ascertained by rectal examination, as already advised by Holmes; and at the same time, carrying the exploration a little further, the feasibility of commanding the circulation through the tumor by digital pressure from the rectum could be determined. In this latter event, to attempt a cure by *distal* ligature would involve less risk to life than the operation of tying the internal or primitive iliac.

I would therefore venture the conclusion, in view of the uncertainty of diagnosis of gluteal aneurism and its generally slow progress, together with the great probability of its traumatic origin and the ascertained difficulty and risk to life of the Hunterian operation, that its employment, in this variety of aneurism, is of doubtful propriety.

Ligature of the external iliac for inguinal and femoral aneurism, in ninety-seven cases collected by Norris, gave twenty-six deaths, or a mortality of about twenty-seven per cent., a comparatively good result, and equal to that attained by compression; so that judging from mortality alone, there is little choice in these localities between the two methods.

According to Holmes's table of cases, the same general conclusion will apply to popliteal aneurism.

Owing to the number and size of the branches given off by the common femoral artery, relapse of aneurism has occurred quite frequently at the groin after obliteration of the external iliac artery, whether by ligature or compression, and this is an argument in favor of the old operation in this locality. It is certainly to be preferred in cases of relapse, and after the failure of flexion, to ligature of the primitive iliac, as Mr. Annandale, of Edinburgh, decided in a case which he has treated successfully within the year by laying open the sac.[2]

The *distal* application of the ligature for the cure of aneurism, as proposed originally by Brasdor, and executed successfully half a century later by Wardrop, after having been for a long period regarded with distrust, is again finding favor. In the well known case of Lambert, it produced a cure of an aneurism confined to the root of the primitive carotid.[3] At the suggestion of Dr. Cockle, of London, Mr. Christopher Heath, in a case of aneurism of the arch of the aorta involving the origin of the left carotid, recently ligated the latter vessel, and the operation

[1] I have since learned that this idea had already been conceived and placed on record by Dr. Frank Woodbury, Resident Physician at the Pennsylvania Hospital. Am. Journ. Med. Sciences, Jan. 1874, p. 131.

[2] Double femoral aneurism treated with success by rapid compression; return of one aneurism; ligature of external iliac, unsuccessful; cure by laying open the sac. Lancet, April 22, 1876, p. 297.

[3] Wardrop, on Aneurism, London, 1825, p. 36.

was followed by shrinking of the aneurismal tumor and decided benefit in relief of symptoms.[1] Mr. Annandale, of Edinburgh, tied the right carotid in a case of aortic aneurism, in March, 1875, and, as I recently learned from him, his patient is still living, and the disease is apparently arrested.[2]

After having failed in four cases of subclavian aneurism, the *distal* ligature has at last been crowned with success in the hands of Prof. Toland, of San Francisco, California. In January, 1874, a miner presented himself with an aneurism as large as his fist, extending from the inner border of the left sterno-mastoid to the anterior border of the trapezius. Two ligatures were applied to the third portion of the subclavian; they came away on the twentieth day. Pulsation in the tumor was perceptibly lessened immediately after the ligature, and gradually decreased up to the sixth week from the date of the operation, after which no pulsation or bruit could be discovered.[3]

Of innominate aneurism there are instances enough on record in which benefit has followed the obliteration of one or both of the branches of this great trunk to warrant Holmes's conclusion that "there are some cases of this disease in which the distal operation is not only allowable, but imperative." Although there are only three cures reputed certain (the cases of Fearn, Evans, and Morrison), of the forty-three he has collected of distal ligature for supposed innominate aneurism, yet the favorable consequences of the operation recognized in studying the individual cases leave a far more favorable impression on the mind than this bare statement would convey. In several of the unsuccessful cases, for example, decided relief to dyspnœa, and to other symptoms, followed ligature of the carotid.

In fact, in a case in which operative interference is decided on, our present experience points to ligature of the right carotid in the first place, as the most judicious course; and to the subsequent consideration of the question of tying the subclavian, and at what part of its course.

Any tendency to spontaneous obstruction of either branch of the innominata should be most carefully sought for, as this "would be a first and grand step towards a cure of the disease."[4] Since Holmes wrote, the double simultaneous ligature, which has never yet succeeded, has been done on a Hottentot in South Africa by Mr. Frederic Ensor; the patient survived more than two months, and died from bursting of the sac.[5] And in another case by my colleague Dr. R. F. Weir, of New York, whose patient did not survive so long.[6]

[3] Western Lancet, July, 1874. Abstract in Amer. Journ. Med. Sci., Oct. 1874.

[4] Surgery of the Arteries. Lettsomian Lectures of the Medical Society of London, 1875, by C. F. Maunder, Surgeon to the London Hospital, p. 25. He refers in this connection to the striking case of Dr. Herbert Davies, in the London Hospital Reports, 1864, vol. i. p. 50, in which the subclavian and its branches were already occluded, so that ligature on the carotid would have completed the cure.

[5] Lancet, Feb. 6, 1875.

[6] In a most interesting case, published within a few days, of an aneurism of the aorta projecting at the root of the neck on the right side and simulating innominate aneurism, Dr. S. Fleet Spejr, of the Brooklyn City Hospital, Brooklyn, New York, obliterated the right carotid by his invaginating "constrictor," and forty-eight hours later applied a silk ligature upon the third portion of the right subclavian. Immediate shrinking of the aneurismal tumor and relief to symptoms followed each of the operations; but inflammation of the sac, taking its origin at the subclavian ligature, with subsequent hemorrhage from this

If the promise offered by the carbolized catgut ligature of Lister, or by the methods of Howard or Speir, be fulfilled, we shall be justified in applying these to the subclavian in the first part of its course. When this can be accomplished successfully, the distal treatment of aneurism of the innominata and also of the aortic arch—in certain cases—will be established as a more hopeful resource to which the sufferer from these formidable affections will be entitled, hereafter, when milder means have failed.

It will be more profitable, perhaps, in connection with the distal treatment of subclavian aneurism, to refer to the recent case in which Prof. Warren Stone, of New Orleans, succeeded in curing a traumatic aneurism involving the second division of that artery by distal pressure applied by the fingers upon its third portion where it crosses the first rib. Its interest will justify a glance at the details of this unique case, for it not only illustrates further the value of the distal treatment of aneurism by ligature, but also that of compression. A healthy man of twenty-five was wounded, in April, 1874, by a pistol ball which entered immediately above the left clavicle, near its inner extremity, and passed downwards and backwards, lodging under the skin at the posterior margin of the scapula. There was great pain, and partial paralysis of the arms, showing lesion of the brachial plexus of nerves, but only a trifling amount of hemorrhage. At the end of six weeks an aneurismal tumor the size of an egg had formed at the cicatrix of the wound, and was steadily increasing. It was attributed to a bruise of the artery at the summit of its convexity. Digital compression by a relay of competent assistants was begun on the 15th of June, 1874, and continued for thirty-nine hours, when the skin began to suffer, and the patient was exhausted. The tumor was reduced to one half its original size, was much harder, and feebler in its pulsations. It continued to diminish and to grow harder from month to month. About the middle of March, 1875, all pulsation had disappeared, and up to the present date it has not returned. The tumor is now as hard as a marble, and quite as small.[1]

This is the only recorded case I have been able to find in which a subclavian aneurism has been cured by distal pressure.

Since the Dublin surgeons re-introduced compression as a remedy for aneurism, and established its value on a permanent basis, it has steadily

point, produced a fatal result in the fifth week. At the post-mortem examination the aneurismal tumor, which sprang from the aortic arch by a narrow opening, was found filled entirely by a "solid mass of coagulated fibrin." The "constrictor" had obliterated the carotid successfully, and the wound had closed perfectly by quick union. See Archives of Clinical Surgery, New York, Sept. 1876, p. 96.

[1] A case of traumatic aneurism of the left subclavian artery treated successfully by distal compression, by Warren Stone, M.D., Professor of Surgical Anatomy, Charity Hospital Med. Coll., New Orleans, from the New Orleans Medical and Surgical Journal, July, 1875. In a private note, under date of May, 1876, Dr. Stone kindly adds the following details to the published case: "I examined the patient a few weeks ago in company with my friend Dr. Choppin. We found a mere remnant of the tumor, with not a particle of pulsation in it. But there was evidence that blood had found its way through the main trunk of the artery (probably by way of the subscapularis), for, by pressing it against the first rib, radial pulsation was arrested, as on the other side of the body." Dr. Stone also adds this interesting fact, since published by Dr. S.: "In Dr. Smyth's successful case of ligature of the innominata—which was also traumatic in its origin—notwithstanding all direct current was cut off, as well as the distal flow through the carotid and vertebral, the sac eventually filled again (taking ten years it is true), suppurated, bled, and caused the patient's death. Post-mortem examination showed that it was principally supplied by the subscapular branch of the axillary."

advanced in the favor of the profession, and has attained new methods and a wider range of application. At first the process was slow, intermittent, painful, accomplished only by mechanical contrivances, and uncertain in its results. Now, thanks to our countryman, Knight, of New Haven, and to the Italian surgeon, Vanzetti, who have taught us the advantage of accurate compression by the fingers, and thanks also to the American discovery of anæsthetics, we are often able to cure aneurism by compression in a few hours. The method has been extended from the femoral, to which it was at first confined, to the largest arteries; where the ligature has failed, it has succeeded; an aneurism of the abdominal aorta has been cured in five hours by compression applied to that vessel; another in ten and a half hours; and an iliac aneurism in five hours of aortic compression—all under anæsthetic influence.[1] The fatal case of Mr. Bryant, of St. Bartholomew's, of rapid aortic compression, in which the patient died of peritonitis,[2] and a similar case of Mr. Maunder, at the London Hospital, in which death occurred suddenly at the fourth hour, apparently from the effects of chloroform,[3] warn us as to the direction in which danger lies. Nevertheless, Mr. Holt has cured an abdominal aneurism at the Westminster Hospital, London, after fifty-two hours' pressure under chloroform.[4]

At first employed only indirectly upon the artery between the aneurism and the heart, compression has also been applied with advantage directly to the aneurismal tumor, as in a successful case of subclavian aneurism, recorded by Mr. Poland,[5] and another of femoral aneurism, cured by Dr. Buckminster Brown, of Boston.[6] In a solitary instance a subclavian aneurism has been cured by digital compression applied to the artery on the *distal* aspect of the tumor—the case of Prof. Stone, already cited; and, in not a few instances, both indirect and direct pressure have been used conjointly in the same case.

Perhaps the most remarkable cure of subclavian aneurism by pressure, is the case published last year by Dr. Tiffin Sinks, of Leavenworth, Kansas. A pistol ball at close range perforated and comminuted the clavicle, and, according to the best judgment of the surgeon, entirely divided the subclavian artery at the commencement of its third portion. The profuse discharge of arterial blood which the surgeon, who was present, saw welling up in a column of three-eighths of an inch in diameter to the perpendicular height of an inch, caused profound and death-like syncope; but the patient, a robust man of forty-six, unexpectedly rallied, and had no return of bleeding. The cylindrical opening through the bone, with its projecting spiculæ, seemed to have fixed the clot which formed during the syncope so firmly that it acted like a stopper, and the result was the formation of a circumscribed aneurism at the seat of injury. Although the pleural cavity slowly filled afterwards in consequence of internal leakage, showing that it also had been opened by the bullet, this ceased after a few days, and the pleural effusion was slowly

1 An account of a case of aneurism of the abdominal aorta, which was cured by compression of that artery immediately above the tumor; by Wm. Murray, M.D., etc., Phys. to the Dispensary, Newcastle-on-Tyne, and Lecturer on Physiology, etc., Med. Chir. Trans., vol. xlvii. 6 Boston Med. and Surg. Journ., Oct. 21, 1875.

absorbed. The compound fracture went on to consolidate, and, strangely enough, the external wound closed entirely without any suppuration, which is ascribed to the fact that no compresses or plugs were at any time applied to it. Eventually a time came when diminution of the general swelling allowed pressure to be applied to the artery just at the outer border of the scalenus, by which the pulsation of the aneurism could be controlled. By the judicious use, at first of intermittent and later of permanent pressure at this point, conjoined with temporary pressure by a mass of lead modelled from a plaster cast of the parts, applied to the tumor itself, all swelling and bruit finally disappeared, so that at the end of three months the patient was able to take a trip to New York on business.[1]

In the form of *acupressure*—by needles, or by metallic wire, what Dr. Pirrie, of Aberdeen, styles "metallic pressure, removable at pleasure"—this remedy of systematic pressure has been subjected to various modifications for the purpose of curing aneurism. In one form it has been applied successfully as a wire compress to the carotid, and again, to the femoral, by Mr. Dix, of Hull, England.[2] Mr. George H. Porter, of Dublin, laid bare the innominata, and compressed it by an instrument of wire resembling a miniature lithotrite, hoping to obliterate the calibre of the artery without dividing its coats; but they ulcerated under the chafing and pressure, and the patient bled to death. I have seen the preparation from this case, and also the instrument. With the latter in a modified form, Mr. Robert Perssé White, of the Meath Hospital, has since cured an inguinal aneurism by compressing the external iliac.[3] Mr. W. Stokes, of the Richmond Hospital, has also applied Mr. Porter's instrument, as perfected by himself, to the abdominal aorta so effectually as to stop accurately the current of blood through that great vessel without injury to its coats, but the patient perished from shock and incipient peritonitis.[4] Mr. Bickersteth, of Liverpool, has also failed in an attempt to obliterate the innominata by means of an apparatus of lead wire and caoutchouc.[5] The so-styled "constricting ligature" of our countryman, Dr. B. Howard, in which a loop of silver wire is applied around an artery so loosely as not to cut through its coats, may also be regarded as a variety of "metallic compression." It is not removable at will, for the wound is closed over it as for quick union, with the belief—founded on experiment—that the little loop will be tolerated by the tissues, and become encysted, and that the inclosed vessel, which is not so tightly constricted as to cause ulceration of its coats, will nevertheless become permanently obliterated.[6]

[1] Medical Herald, Leavenworth, Kansas, Aug. 1875, p. 15.

[2] Two cases of aneurism, one of the carotid, and one of the femoral artery, treated by the wire compress, by J. Dix, M.R.C.S., etc. etc., in Brit. Med. Journ., August 28, 1875. Mr. Dix cuts down upon the artery, and introduces a strand of flexible iron wire beneath it in the usual way by the aneurism needles. Each end of the wire is then threaded to an ordinary needle, and brought out through the tissues by the side of, but clear of, the wound, which is then closed entirely as for healing by first intention. A piece of cork is then placed between the two points of emergence of the wire, and pressed down firmly upon the artery, and over this cork the wire is tightly twisted until the circulation is stopped. At the end of six or seven days the wire is withdrawn.

[3] Dublin Medical Press, November 24, 1875, p. 428. In this case, the artery is stated to have been compressed one hundred and sixty-two hours, and yet there was no ulceration nor hemorrhage.

[5] Holmes's Lectures, ut supra.

[6] An Essay on the treatment of Aneurism by a new method, with experiments upon the closure of arteries. By Benj. Howard, M.D., late Prof. of Clinical Surgery, etc., from Transactions of Amer. Med. Association, 1870.

Dr. S. Fleet Speir, of New York, has also devised an ingenious artery compressor which can be applied upon the continuity of an artery, so as to divide the middle and inner coats, and then to invaginate the external coat of the artery within the tube of the constricting instrument to a sufficient extent to roll up the two inner arterial tunics into an impassable barrier equally efficient with that produced by the method of torsion. After this, the instrument is withdrawn, and the wound closed. This ingenious device has been successfully applied to the carotid three times, to the femoral and the brachial, each, once; in each instance it has caused obliteration of the artery, and, as Dr. Speir informs me, has in four cases caused a cure of aneurism.[1]

On the whole, the results of compression by metallic wire have not been very satisfactory in any of its modes of application, so that, at the time he wrote, Mr. Holmes felt justified in asserting that, for his part, whether Mr. Lister be right or no in saying that, with the carbolized catgut ligature properly applied, the ligature of the innominata will be found a safe proceeding, he, Holmes, would much prefer tying that vessel on this method to making any attempt at acupressure.[2] But, although he alludes to a case in which he used a wire ligature successfully, Mr. Holmes does not mention B. Howard's method.[3] In my judgment, we cannot afford to ignore this method of employing silver wire, for, in case the carbolized catgut ligature should in the end prove unreliable, it seems to me that Howard's suggestion, and the invaginating constrictor of Speir, hold out the best remaining promise of occluding an artery without dividing its coats.

But the most interesting case of metallic compression has occurred since the date of Holmes's lecture: it is that in which Mr. Arthur Ferguson McGill, of Leeds, succeeded in consolidating an aneurism of the left subclavian artery by means of a pair of ordinary artery forceps applied to its first division for ten hours. Unfortunately, in consequence of the anomalous position of the vessel, the pleura was wounded, and through this accident he lost his patient.[4] In this case the efficacy of

Hart; New York Med. Record, March 1, 1873, p. 102, and March 15, 1873, "The artery-constrictor, with cases, by Dr. Speir."

[2] Holmes's Lectures, etc., ut supra.

[3] Holmes says of this case, in which he tied the femoral artery for popliteal aneurism with silver wire, that it was "thoroughly satisfactory," the wound healing, though not without suppuration, in less than a fortnight. Nothing was seen of the ligature; and he believes that it "buried itself in the tissues of the vessel, and in all probability without having divided the continuity of the latter;" Lect. iii., Part i., 1st series, June, 1872. He also speaks of an experiment upon an ass, in which the carotid was obliterated and not divided, and adds a caution about not tying the wire too tightly, lest it cause ulceration.

[4] A case of left subclavian aneurism, treated by temporary compression applied directly to the artery in the first part of its course, with remarks; by Arthur Fergusson McGill, F.R.C.S., surgeon to the Leeds Public Dispensary, Med.-Chir. Trans., vol. lviii. p. 338, London, 1876. A woman of 35, with a left subclavian aneurism, had already been very decidedly benefited by four applications of galvanic needles, but she had resumed a laborious occupation and the tumor began to grow again, and the pain of the shoulder and arm which had been relieved by the galvano-puncture returned. The tumor had extended above the clavicle into the neck, and was approaching the surface. She was too poor to spare the time to try Tufnell's medical treatment, and refused amputation of the shoulder, which had been proposed in consequence of its partial success in Mr. Spence's case. Mr. McGill had no confidence in the distal ligature without amputation, and makes no mention of distal compression. He, therefore, proceeded to cut down upon the artery in the usual way, failed to find it in its usual place on following down the inner border of the scalenus anticus, but discovered it after a tedious search at the depth of his finger, "apparently through a layer

rapid pressure by a metallic substance applied directly upon an artery is indisputable, for the subclavian, in its first portion, was certainly obliterated without division of its coats, and, therefore, without danger of subsequent hemorrhage; and it may be fairly assumed that the aneurism would have been permanently cured, but for the fatal wound of the pleura.

This brings us to consider the propriety of attempting the ligature of the left subclavian in the first part of its course. Holmes briefly passes it over as an operation not likely to be again undertaken on account of its great difficulty, the danger of wounding the pleura, and, perhaps, because Sir Astley Cooper once relinquished an attempt to tie this artery through fear of wounding the thoracic duct. But Rodgers accomplished the ligature of the artery at the New York Hospital safely, without wounding either thoracic duct or pleura. Unfortunately, his ligature of silk cut through the walls of the artery, and his patient died in the third week from secondary hemorrhage. McGill, hoping to obliterate the artery by employing metallic compression in place of the silken thread, and thus to surmount this danger, felt justified in repeating the operation; and he succeeded in his object of safely obliterating the artery and avoiding the danger of hemorrhage; but, less fortunate than Rodgers, the anomalous position of the vessel led to the perforation of the pleura, and this accident caused the death of his patient.

Now, is the danger of wounding the pleura in this operation so unsurmountable as to forbid its repetition? This question must be answered, for if, in the future, it becomes certain that we may trust the carbolized catgut ligature (or even Howard's constricting loop of silver wire) to safely obliterate an artery without dividing its coats, then the risk incurred in laying bare the left subclavian would be the only remaining obstacle to its successful ligature. I feel confident that others will undertake this operation, under the lead of Rodgers, as McGill has done; and as neither of these excellent surgeons had any trouble from the thoracic duct, we have only the danger of wounding the pleura to provide against, and the other intrinsic difficulties of the operation.

My late valued friend, Dr. Charles E. Isaacs, after Dr. Rodgers's operation in 1845, "in order to improve our knowledge as to the relations of the pleura to the parts at the root of the neck," examined in a series of years no less than one hundred dead bodies most carefully in reference to this point of anatomy. He found that the pleura rises higher above the clavicle than is usually recognized by anatomists, averaging in his 100 cases nearly an inch and a half at its highest point, whilst in 23 out of the 100 it rose to two inches and upwards; and that both subclavians within the scaleni muscles are in contact throughout their whole length with the pleuræ. The reason why the pleura has not been more fre-

of pleura" which, in passing the needle around the vessel, was perforated. He then effected compression of the artery by means of a pair of ordinary torsion forceps, stopping effectually all pulsation in the tumor, and closed the wound. Three hours later the pulse was 130; respiration 44; and the air was rushing in and out through the wound as she breathed; but the artery was effectually compressed, and when, ten hours after its application, the compressing forceps was withdrawn in consequence of the patient's feeble condition, so that the wound could be entirely closed, the tumor was solid and pulseless. She died on the sixth day from intra-thoracic inflammation, just as death occurs from a perforating chest wound. The pleura contained a pint of bloody serum. The aneurism was filled with a hard firm clot; in fact it was cured. "The artery had been compressed just before the origin of the vertebral; it was patent, and in a perfectly healthy condition." (p. 341.)

quently wounded in tying the right subclavian in its first division is, he thinks, because the vessel is nearer the surface, and can usually be seen.[1]

Now, the surgeon, as he approaches the first division of the left subclavian from above and in front, as it rises almost perpendicularly from the aorta to arch over the dome of the pleura, unless he fully recognizes the facts brought out by Isaacs, and systematically pushes the serous membrane out of his way, just as we are compelled to raise the peritoneum in approaching the primitive iliac, must incur great risk of perforating it; but an accurate anatomist, keeping these relations of the pleura always in view, may, as Rodgers did, accomplish the operation safely.

In cases where an aneurism is seated near a joint, so that its pulsation can be arrested by maintaining the limb in a flexed position, this simple device continues to be successfully employed, as another variety of compression, under the designation of "the method by flexion," or "position." It has been used most frequently at the knee-joint for popliteal aneurism, but Dr. Gurdon Buck, at the New York Hospital, extended its application to a case of inguinal aneurism which he cured by flexing the thigh upon the pelvis. This was a case of relapse, such as is liable to occur in this region, the aneurism having returned sixteen months after a cure by compression. Pressure upon the external iliac did not arrest the returned pulsation; the vessel in fact had been obliterated. Its ligature, therefore, was out of the question, and the old operation seemed to be the only alternative, as in the similar case of Mr. Annandale already mentioned. Buck had observed, however, that extreme flexion of the thigh arrested the pulsation in the tumor, and he decided to employ this method. In about a fortnight solidification was nearly complete, and an entire cure shortly followed.[2] In a case of femoral aneurism treated first by compression, without result, and finally by ligature of the external iliac, Dr. Gay, amongst other devices to arrest the circulation, tried flexion of the thigh upon the abdomen, which controlled it completely; but it was abandoned in six hours on account of the pain. The parts had become tender under the previous digital and instrumental

[1] Isaacs, "on the extent of the pleura above the clavicle," in Transactions of the New York Academy of Medicine, vol. ii., part i., New York, 1857. Isaacs ascertained that in 100 subjects the pleura averaged 1.42 inches above the upper margin of the clavicle on the right side, and 1.23 on the left. It averaged higher in the male than in the female—1.53 to 1.40. In 23 cases it rose to two inches and upwards above the clavicle, and there were only 5 out of the 100 in which the pleura did not project above its superior margin. The sternal or internal aspect of the pleura of the right side extended across, even to the left of the median line, in 11 cases, from half an inch to an inch and a quarter. A similar disposition of the parts was never observed on the left side. The pleura rises higher in long-necked people; in bull-necked subjects the reverse is the case. In the 23 cases in which the pleura rose two inches above the clavicle, 14 were on the right, 5 on the left, and 4 only on both sides. In these cases the subclavian was high in the neck, and in many of them this artery in the third part of its course rested upon the pleura for a very considerable extent. He asks if the symptoms of wound of pleura and collapse of lung in operations at the root of the neck have not been falsely attributed, in some cases, to entrance of air into the veins? Erichsen states that thoracic inflammation was the cause of death in 9 out of 22 cases of extra-scalene ligature of the subsclavian arteries, and that it was not the pneumonia which so often follows great operations, but inflammation attacking the pleura and pericardium in preference to the substance of the lungs, looking as though the complication arose from causes essentially connected with the disease or operation. Isaacs thinks that one of these causes is probably the unrecognized proximity of the pleura, which he shows exists in one case out of every four. He also speaks of "the curious fact that the top of the pleural sac is not always dome-shaped, but sometimes forms cul-de-sacs extending upwards, and sometimes laterally into the recesses at the root of the neck." (p. 18.)

[2] Amer. Journ. Med. Sciences, January, 1870, p. 69.

pressure.[1] In the case of a Japanese of 40, who was too fat for compression of the external iliac, and unwilling to submit to ligature, Dr. Stuart Eldridge, of Yokohama, succeeded in curing an inguinal aneurism by this method. He devised an apparatus consisting of a jacket and thigh-sheath connected by copper wire, in which the thigh was kept flexed on the pelvis for twenty days, at the end of which time pulsation had permanently ceased. The patient was seen six months later, and there was no return of the disease.[2] Dr. Edward T. Caswell, of Providence, R. I., reports a case of double popliteal aneurism in which genuflexion short of completely arresting the circulation cured both tumors. At the end of six weeks, during which time the man had resumed work, one of the tumors suddenly returned (evidently by rupture), and, after failing with ordinary compression, it was necessary to tie the femoral. There was subsequent suppuration, and discharge of clots.[3] In April of the same year Dr. Montgomery cured a traumatic aneurism at the bend of the arm by simple forced flexion of the forearm upon the arm for twenty-four hours.[4]

From these facts we may infer that this method is still in favor, and certainly gaining in extent of application, for heretofore it has been confined to aneurisms at the knee and elbow; and also that, when tried, it should precede compression by ordinary means, which are liable to leave the parts tender. It is well to remember, also, that Theodore Maunoir, of Geneva, who reported the first case of cure by the method of flexion, in 1858, demonstrated that the position need not be forced or painful, but that, as in ordinary compression, a very moderate obstruction to the circulation may effect a cure.[5]

To conclude the subject of pressure, it is evident that digital compression is steadily gaining ground and taking the place, wherever it is applicable, of pressure by means of mechanical appliances; and also that the process known as "rapid compression," under anæsthetics and anodynes, is increasing in favor.

Still, we must not forget that the old method by moderate and intermittent pressure has also from time to time effected striking cures, and these in localities—as, for example, upon the primitive carotid—where it cannot be safely replaced by more permanent or rapid pressure. The following cases of orbital aneurism are in point: that of Galezowsky, who cured a traumatic case in an adult female by digital compression applied to the carotid, for an hour or so every day at first, and afterwards at longer intervals, for several months.[6] In Scaramuzza's case of idiopathic orbital aneurism a cure followed digital compression, employed very cautiously on account of aortic disease, for not more than five minutes at a time, and afterwards for eighteen days, twenty or thirty minutes every day in five or six turns—the total period of compression being only seven hours and twenty minutes.[7]

I have noticed amongst hospital surgeons of experience a tendency to allow intelligent patients to manage pressure for themselves, by means of bags of shot, or of sand, or by a mass of lead modelled to the part, and gradually increased in weight. At St. Thomas's Hospital, in London, I saw a man in Mr. McCormac's ward with a subclavio-axillary aneurism, who was successfully controlling its pulsations by a buckskin bag of shot,

to which he had given a peculiar shape; and Prof. Tilanus, at the principal hospital of Amsterdam, showed me a weight of three kilogrammes, by which, he said, several cases had been treated in this way.

If time permitted, the subject of *orbital aneurism* might occupy us profitably. Mr. Rivington, of the London Hospital, has lately made a very thorough study of this curious and obscure affection in connection with a case which he finally cured by ligature of the carotid.[1] Dr. Morton, of the Pennsylvania Hospital, by his unusually rich experience, has also added to our knowledge of this subject. His last published case illustrates the great difficulty that often attends its diagnosis—already shown in the cases recorded by Bowman,[2] and by Aubrey, of Rennes,[3] in both of which, with unmistakable symptoms of aneurism—such as pulsation, bruit, and protrusion of the eyeball—no arterial lesion whatever was found after death. In Dr. Morton's case, with all the characteristic symptoms of orbital aneurism, except pulsation in the protruded globe, symptoms sufficient to warrant the diagnosis of aneurism of the internal carotid in the cavernous sinus, and ligature of the carotid, no trace of aneurismal disease was found after death on the day following the operation.[4] It is to be noted that in each of these cases ligature of the carotid produced immediate relief of the symptoms.

Mr. Holmes, as usual, discusses this subject ably in his lectures.[5] In view of the great uncertainty of diagnosis, and the possibility also of a spontaneous cure—such as took place in the cases recorded by France,[6] Collard, of Berne,[7] Erichsen,[8] and I may add also a more recently reported case of Mr. Jonathan Hutchinson,[9] together with the admitted dangers of the operation, he urges delay in resorting to ligature of the carotid. At the same time, whilst reasoning against it, Holmes speaks of the operation in this affection, in his Surgery, as "a most successful one;" and it is noteworthy that the delay which he advised in Rivington's case led to more loss of vision, and that the ligature was resorted to, of necessity, in the end.

In a still more recent case of Dr. Greuning, of New York, diagnosticated as aneurism of the internal carotid in the cavernous sinus, the operation was promptly and entirely successful.[10]

Mr. Rivington arrives at the conclusion, derived from his very complete collection of cases, that "ligature of the carotid is, beyond question,

[1] A Case of Pulsating Tumour of the Left Orbit consequent upon a fracture of the base of the skull, cured by ligature of the left common carotid subsequently to injection of perchloride of iron, after digital compression and other means of treatment had failed; with remarks, and an appendix containing a chronological résumé of recorded cases of intra-orbital aneurism. By Walter Rivington, etc. etc., Surgeon to the London Hospital. Read March 3, 1875, published in Med. Chirurg. Trans., vol. lviii. p. 183.

[9] A pouched aneurism of the internal carotid as large as a bantam's egg was found at the post-mortem examination of a woman of forty, who had died of aneurism of the abdominal aorta. Ten years before, Mr. Hutchinson had seen her with ptosis of the eyelid of this side, dim vision, paralysis of the ocular muscles, except the superior oblique, intra-cranial bruit, throbbing, and bad headaches. He had diagnosticated intra-cranial aneurism, and advised ligature of the carotid, but had been overruled, and spontaneous cure followed. British Med. Journ., April 17, 1875.

[10] Archives of Ophthalmology and Otology, vol. v. No. 1, p. 40.

the means most generally applicable to cases of intra-orbital aneurism dependent on morbid states of the arteries." His cases give forty-six instances of ligature of the carotid in forty-four cases (two being double), and six deaths.[1] With such experience, ligature of the carotid in orbital aneurism will continue to be employed, even though in some degree empirically.

I may record the fact that our countryman, Dr. McGill, of Maryland, was the first to tie both carotids in this disease.[2] Erichsen places his name second on his list of double ligatures of the carotid, for all causes. Dr. Foote, of Cincinnati, also tied both carotids at the same interval of a month, arresting a traumatic orbital aneurism at the second ligature.[3] It is proper to observe, in concluding my remarks under this head, that ligature of the primitive carotid for aneurism *other than orbital*, has proved a very fatal operation, mainly through embolism and interference with the blood-supply of the brain, probably less than half the cases on record having been successful.[4] The evidences, therefore, in favor of compression of this vessel, collected by Mr. Holmes, carry great weight. Of his seven cases, five were cured; and in the two in which compression did not succeed, the ligature also failed.[5]

Galvano-puncture, as a method of treatment for aneurism, can hardly be said to be gaining rapidly in the confidence of the profession, perhaps mainly on account of the intrinsic difficulties which attend the process; but, as has been truly said, it occupies at the present time a more promising position than did compression in the days of Guthrie, who did not hesitate to speak almost contemptuously of the pretensions of the latter. The promise held out by the relief of pain and the arrest of pulsation, which so often follow an electrolytic operation, is not fulfilled with certainty; for after a short interval the pulsation almost always returns. This disappointing result seems to be due to the softness and friability of the resultant clot, which is broken and wasted away by the arterial current. We have learned, however, that this soft clot possesses

[1] Of these 44 cases, 25 were cured—one after subsequent injections (case of Brainard of Chicago; Lancet, 1853, p. 162, vol. ii.), 7 received partial benefit, 5 were unsuccessful, and 6 died. Two of these deaths were in patients over sixty years of age, and two others (cases of Critchett and Pétrequin), in patients who survived several weeks, and died eventually from other causes, are not chargeable to the operation.

[2] In a letter to the late Dr. J. Kearney Rodgers, of New York, from Dr. Joshua J. Cohen, of Baltimore (in the N. Y. Med. and Phys. Journ., Sept. 1825, p. 576), it is stated that in this case "an ugly, confused mass protruded beyond the sockets of both eyes," and was increasing every day. The operations were done at an interval of about a month. Dr. McG. found the effect of tying one carotid to be limited to one tumor, and ventured upon the bold attempt (in which he had but one precedent, and probably was not aware of that) of arresting the progress of the other by tying the remaining carotid. Several months after the last operation the patient was doing well, and the tumors subsiding. At this early date there were no recorded examples of successful ligature of the carotid for tumors about the head except the cases of Travers (1809), and Dalrymple (1812), in both of which the disease was supposed to be "aneurism by anastomosis." Doubtless Dr. McGill regarded his case as of the same nature. Cases of soft cancer protruding from both eyes, and doing well some months after ligature of both carotids, are not of probable occurrence, whilst double aneurism has existed in several instances.

Since the above was written, I have seen a note from Dr. Charles McGill, of Richmond, Va.; dated June 9, 1876, in which he writes as follows: "In 1823 my brother ligated both common carotids of a woman in Williamsport, Md., for vascular tumors of the orbits. The interval between the tying was about four weeks. The operation was successful, and the woman was still living and in good health in 1861, when I left the State of Maryland."

[3] Reported by Dr. E. Williams, in New York Med. Record, April, 1868, p. 75.

[5] Op. cit., Lect. ii., second series, June, 1873.

neither noxious nor irritating qualities, so that the operation, which is better done under an anæsthetic, may be repeated indefinitely.

We owe to Dr. John Duncan, of Edinburgh, the knowledge that inflammation of the sac, the principal danger that attends the process, is not to be feared if there is no cauterizing effect produced by the needles, and that this can be certainly avoided if they are effectually insulated by a coating of vulcanite—a device introduced and perfected by Dr. Fraser and himself. "I have never met with the slightest reaction," says Duncan, "when using insulated needles; and in one case I continued the operation for two hours and ten minutes."[1]

This being the case, the eschars and fatal hemorrhages, and inflammation and suppuration of the sac, which complicated some of the earlier cases of galvano-puncture, can be now surely escaped, and we have only the uncertainty of the result to contend against.[2]

The plan of operating which experience seems to point out as the best, is to insert both the positive and negative needles, thoroughly insulated by means of vulcanite, into the sac; to employ a battery of large electromotor force; to prolong the operation so that the sac may be occupied as fully as possible by clot; and, finally, to repeat the application as soon as improvement shall have distinctly ceased.

Perhaps the best idea of the value of the electrolytic treatment can be got from Holmes's abstract of the cases of Ciniselli, of Cremona, who has employed it more largely than any other surgeon. In these, twelve in number, there were two relapses after many months of good health, one of which was permantly cured by repetition of the operation, and three other cases in which a cure had been maintained for still longer periods at the time of the report. Of the eight cases which were not benefited, in only one was death caused by the direct action of the electricity, and no harm seems to have followed its use in the others.[3] Abeille cured a case of subclavian aneurism in a woman, having kept a weight of one kilogramme upon the tumor for ten hours after the application of the needles.[4]

The great point in favor of this method is that it may be applied to thoracic and abdominal aneurisms where other surgical remedies are powerless, in combination, for example, with Tufnell's medical treatment. In thoracic aneurism, both Ciniselli and Duncan have certainly succeeded in averting imminent death from hemorrhage where the tumor was already projecting beyond the ribs.[5] In abdominal aneurism no success has been as yet attained. In Keyes's case the manœuvre was accomplished safely, but without apparent result beyond relief of pain.[6] In Dell'

[1] Lectures on Electrolysis, by John Duncan, M.D., etc., Assistant Surgeon to the Royal Infirmary, Edinburgh, Lecturer on Surgery, etc.; British Medical Journal, June 28, 1876, p. 621.

[2] See the case of Pétrequin (Journal de Chirurgie de Malgaigne, t. iv. p. 246, 1840), and another case in Broca (sur les Anévrysmes, etc., Paris, 1856, p. 342), in which the needles, uninsulated, were applied seven times in one week for an aneurism under the jaw; there was no consolidation, but inflammation and suppuration followed, with secondary hemorrhage, necessitating ligature of the carotid, and free opening of the sac, and other measures to stop the bleeding.

[3] It is proper to note that Ciniselli's mode of operating is probably more liable to irritate and inflame the sac than when insulation by vulcanite is employed.

[4] Archives Générales, t. xx. p. 49, 1849.

[5] Lectures, etc., ut supra.

[6] New York Med. Journ., December, 1871, p. 569. Keyes demonstrated, however, that eleven needles could be passed through several layers of peritoneum and convey the current from thirty-two cells (of a Stohrer's battery) without causing inflammation. His needles were insulated by vulcanite.

Acqua's case the aneurism burst during the struggles of the patient under chloroform, and he died on the table.[1] McGill reported a case of subclavian aneurism as greatly benefited after four operations, manipulation having been also employed conjointly with electrolysis after the last application. But relapse took place, and nine months later the woman was subjected to the operation on the left subclavian already reported.[2]

As to galvano-puncture in external aneurisms, Ciniselli cured a popliteal case in 1846—the second recorded example of success by electrolytic treatment, Pétrequin, of Lyons, having cured a small aneurism of the temporal artery the year before.

Broca, in external aneurisms, recommends direct moderate pressure to be applied immediately after the withdrawal of the needles, with the view of its effect upon the tumor in the way of malaxation, or manipulation, as it was employed, in fact, in Abeille's successful case of subclavian aneurism; and this seems to me an excellent practical suggestion. An Esmarch's bandage for example would really offer the best means of effecting distal pressure (which in the leg and forearm is not easy to accomplish) during the operation, and, if it were afterwards carried upwards over the whole limb including the tumor, it might materially assist in preventing the liability to washing away of the clot.

Dr. Duncan says, in his summary of conclusions, that "in external aneurisms electrolysis should be tried, if compression be not available, or have failed; and it is to be preferred to the ligature—at least of the innominate and iliac arteries."

In his address on Surgery before the British Medical Association, in August, 1875, Prof. Spence, of the University of Edinburgh, stated that his colleague Dr. Duncan had had successful results in treating large cirsoid aneurisms by electrolysis. There is additional evidence on this point in Dr. Duncan's lecture since published.[3] It is also very generally conceded that for most forms of aneurism by anastomosis, and erectile tumors, electrolytic treatment offers, at the present time, greater advantages than any method of treatment in use.

Manipulation, one of the bloodless methods of treating aneurism, with which the name of Sir William Fergusson is principally connected,[4] has not yet achieved credit for the success which it seems to promise and to deserve. According to Holmes, this method has been practised in five cases of subclavian aneurism, and in two of aneurism of the lower extremity, "with clear evidence of cure in two, and a good advance towards cure in another," and no certain proof of injury to the sac, which is the great danger of the proceeding, in any case.[5] This surgeon has proved by carefully studied preparations and cases that

[1] Gazetta Medica Italiana, Lombardia, No. 28, 1870, p. 217.

[2] My colleague Dr. Sands, with the aid of Dr. Guleke, attempted to arrest the progress of a traumatic subclavian aneurism in a young man of nineteen, at the N. Y. Hospital, in March, 1869. He made four electrolytic operations of fifteen minutes each, following Ciniselli's method mainly. The tumor became momentarily firmer, but it continued to enlarge, and finally burst. (Thesis of Dr. Allan McLane Hamilton, New York, 1870.)

[3] British Med. Journ., August, 1875, p. 189. In the same Journal, June 10, 1876, p. 715, Dr. D. says: "There are four recorded cases in which electrolysis has been used in cirsoid aneurism, and in three the disease has been cured. In a case in which Syme declined to operate, six applications of the battery effected a cure."

[4] Med.-Chir. Trans., vol. xl.

[5] Op. cit. Lect. v. Part i., 1st series, 1872. I do not think that Dr. Lidell's successful case is among these.

impaction of clot in the distal end of the artery as it leaves an aneurismal sac is naturally (not always necessarily) followed by obliteration, more or less complete, of the sac. The curative effect of the distal ligature is thus explained, and also that of the method we call manipulation. By the latter proceeding a portion of clot is intentionally and by violence detached from the internal wall of the aneurismal sac, and pushed by the fingers, or carried by the current, into its distal outlet, so as to plug it like an embolus. A large proportion of the cases in which aneurism is said to undergo spontaneous cure are doubtless brought about in this manner, and Sir William Fergusson has wisely recognized Nature's lead in proposing it as a remedy.

I think that many cases reach their final cure in this manner after the interference of art, in which the real *methodus medendi* is not recognized, or is referred to some other cause. Take, for example, the cases collected by Mr. Tufnell, at page 89 *et seq.* of his excellent "Practical Remarks on the Treatment of Aneurism by Compression," published in 1851, in which, after a certain amount of contraction and hardening of the tumor, this treatment seemed powerless to arrest pulsation entirely, and the patients, as the disease had ceased to increase, were sent about their business. In every such instance in which the patient was followed up, a final cure was found to have taken place, and it had always occurred suddenly and after some unusual effort, when a new, painful sensation would be felt in the tumor, and presently all pulsation would be found to have ceased. Here, I take it, a fragment of clot had become detached and plugged the distal outlet of the half-cured aneurism.

This method of cure is only applicable to aneurisms in which a certain amount of clot has already formed, and of which the walls present, as yet, no evidence of thinning or softening, so as to endanger rupture by handling. Dr. Bontecou, of Troy, recently tied the external iliac in a case of inguinal aneurism, which had been ruptured by the manipulation of a professional rubber, undertaken for the relief of pain.[1] A prominent medical man of Dublin caused the rupture of an abdominal aneurism in his own person. He had known of its existence for ten years, and it had undergone partial cure. The object of his manipulation was to convince his attendants that it was a mass of hardened feces, for, when he grasped the tumor and drew it away from the spine, its pulsations were arrested. Shortly after they had retired to consult, he was found dying from internal hemorrhage.[2] These examples teach us the necessity of caution.

Manipulation of an aneurism of the innominata or of the primitive carotid might occasion cerebral embolism, and inflammation of the sac is always a possible contingency.

It has seemed to me that in one, if not both, of the remarkable cases of apparently spontaneous cure of subclavian aneurism recorded by the late J. Mason Warren, of Boston, the violence previously inflicted upon the tumors was the real means of cure, by causing fragmentation and distal impaction of organized coagula.[3] And this is also the most probable explanation of the success of Staff-Surgeon Reid in the interesting case of popliteal aneurism in which, after failure of compression by ordinary methods, he effected a cure in fifty minutes by the application of an Esmarch bandage.[4] His patient subsequently died within the year of visceral disease; and, in describing the condition in which he found the

[4] Lancet, Sept. 25, 1875.

cured aneurism, Dr. Reid speaks of the manifest displacement of the fibrinated laminæ which it contained, which laminæ were probably due to the previous attempts at its cure by compression.[1]

I have been able to find no very recent cases in which the use of *coagulating injections* has led to satisfactory results, except a case ascribed to Plagge, of Darmstadt, who cured a traumatic aneurism, just below Poupart's ligament, by injection of extract of ergot, alcohol, and glycerine, continued daily for three weeks, with an ice-bag applied to the tumor in the intervals.[2] The use of ergot is ascribed to Langenbeck, and the absence of details detracts from the value of the case. In the case of Dr. Dutoit, of Berne, the cure of an aneurism supposed to be subclavian, in a man of 40, is attributed to fifteen injections of a solution of ergotin into the tissues immediately over and around the tumor, at intervals of two or three days. This caused diminution or shrinking of the tumor, and subsequently indirect digital pressure was employed to confirm the cure.[3]

The danger of embolism, of which so many instances have followed the injection of erectile tumors by the perchloride of iron, has apparently inspired a fear of using this drug in the sac of an aneurism; whilst its known escharotic qualities, and the hardness and irritating nature of the magma of iron and blood-salts with coagulated albumen and blood-corpuscles resulting from its use, have deterred surgeons from employing it, through well-founded apprehension of inflammation in and around the sac.

In the case of Lenoir, after a third injection which, like the previous ones, was apparently ineffectual, solidification of the tumor took place unexpectedly, and inflammation forthwith developed itself in the sac, and resulted fatally.[4] Here coagulating injections failed, but inflammation caused consolidation of the aneurism, and unhappily also the death of the patient.

In cases where coagulation by the perchloride has succeeded, the resultant mass takes on an almost calculous hardness, fails to be absorbed, and either becomes permanently encysted, or excites suppuration to secure its expulsion as a foreign body.

The question is pertinent whether the tissues would tolerate any better a clot produced by the *persulphate* of iron.[5] This substance, which is not escharotic, has been used by the late Dr. Isaacs, of New York, and also by Drs. Minor, Hutchison, and Enos, of Brooklyn, with success in injecting varicose veins.[6] In July of the present year, Dr. J. C. Hutchi-

[1] Lancet, Aug. 5, 1876. Dr. Reid says in substance that the portion of the cavity of the aneurism apposite its mouth was occupied by several layers of laminated fibrin. Some of these were partially separated from the others and approximated towards the centre, the interspace thus caused being filled by an amorphous, softer, cheesy coagulum.

[5] Or subsulphate, as I believe it should be called. I mean the salt of iron which is the basis of Monsel's solution.

[6] I learn from Dr. James M. Minor, and also from Dr. Squibb, of Brooklyn, that in experiments with this salt of iron they have been impressed with its great harmlessness, and even with its healing properties when in contact with the tissues. Dr. Minor has published six cases in which it has been used successfully—one, a pulsating (erectile) tumor, and five cases of varicose veins. See American Medical Times, July 1st, 1860. He employed a Pravaz syringe, and a solution containing four parts of distilled water to one of the salt, which, he thinks now, was too strong, as Dr. Jos. C. Hutchison, of Brooklyn, since informs him that he has used it successfully in a solution of thirty to one, without exciting ulceration in any case. (Private communication of this date.)

son, at the Brooklyn (N. Y.) Hospital, injected a large and increasing aneurism of the abdominal aorta in a sailor of thirty-two, three times, at intervals of two or three days, with thirty minims of a solution containing about half a grain of this salt. Death followed within a fortnight with symptoms of inflammation of the sac (*i. e.*, local tenderness, increased temperature, 103°, frequent pulse), and subsequent rupture. There was much stratified fibrine in the sac, apparently recent. (From notes of case as recorded by house surgeon.)

Brainard, of Chicago, cured an orbital aneurism by injecting a solution of lactate of iron, after ligature of the carotid had failed; but destructive inflammation followed.[1] Bourget used the perchloride successfully in what seems to have been a cirsoid aneurism following injury, in a boy of twelve, after failure by galvano-puncture.[2] Desormeaux had similar success in an adult.[3] Pétrequin lost a case, but apparently from causes unconnected with the injection.

Embolism has not occurred in any of the cases of orbital aneurism treated by coagulating injections.

Broca records his success in the injection of large vascular trunks of cirsoid aneurism of the scalp, where accurate pressure could be made upon the vessel on either side of the portion injected.[4]

Our best hope for the future success of the operation of Pravaz would seem, at present, to depend upon the results of experiments with the persulphate of iron, in solutions of different strength, in cases where accurate pressure can be made on both the cardiac and distal aspects of the aneurismal sac.

Closely allied to the use of coagulating injections as a remedy for aneurism is the idea of inserting foreign material into its cavity in order to provoke, mechanically, the deposit of fibrinous clot. The earlier attempts in this direction, inaugurated by Moore, of Middlesex Hospital,[5] London, who employed fine iron wire, and whose example was followed by Domville and Murray, failed in each instance, because the wire produced inflammation of the sac—a result which was no doubt anticipated. Dr. Levis, of Philadelphia, ingeniously substituted an animal substance for the more rigid and irritating metallic wire, and inserted twenty-four feet nine inches of horsehair through a fine needle canula into a subclavian aneurism, in a man of twenty-seven, at the Pennsylvania Hospital in October, 1873. The tumor became hard, and the pulsation in it and in the radial artery, ceased at once. The man died during the month from internal hemorrhage, when it was discovered that the sac of the aneurism had already ruptured previous to the operation, and that a part at least of the walls of the cavity into which the horsehairs had been inserted was formed of lung tissue. Notwithstanding this untoward condition, their presence had caused the formation of hard clot, and obstructed the flow of blood into the axillary artery, solidifying the portion of the tumor which projected above the clavicle, and causing entire cessation of the radial pulse. There were no evidences of inflammation caused by the foreign body.[6]

The conclusion can hardly be avoided, in this interesting case, that if

there had been a true resisting sac to the aneurism, a cure would have followed.

This operation has been repeated by Mr. Bryant, of St. Bartholomew's Hospital, London, who introduced twenty feet—three hairs at a time—into a rapidly-growing popliteal aneurism, "with the effect of causing almost complete consolidation of the tumor. The man survived the operation five days, dying from ulcerative endocarditis, a condition that existed before the operation." This surgeon considers these results as quite sufficient to justify a repetition of the operation.[1]

If we succeed in getting a preparation of catgut somewhat more permanent than that now in use for ligatures, but still capable of blending ultimately with the tissues, the use of this substance would be still less likely to provoke inflammation or suppuration.

Finally, there is still a variety of aneurism to which experience has taught us that the Hunterian operation is inapplicable; but the lesson is being learned slowly. I refer to the cases in which an abnormal opening has been formed between an artery and vein—what we call arterio-venous aneurism, a term properly used whether any tumor be present or not. This affection is almost invariably the result of a wound, and is characterized by an exaggerated and peculiar thrill[2] often perceptible in the neighboring veins, and also by enlargement in calibre of the arteries involved, and thinning of their walls.

The Hunterian ligature has been wrongly applied to the cure of this affection, as is proved by the occurrence of gangrene or secondary hemorrhage in all the cases in which it has been done in the lower extremity, and in some cases in the upper. Unfortunately it has had the sanction of Scarpa, Hodgson, Physick, and Liston. The rarity of its occurrence explains the delay in accumulating experience enough to reverse this authoritative endorsement. But on the other side we have Dupuytren, Breschet, Mott, and Norris; and, in addition, we have this great fact, which experience has taught us, that this form of aneurism is not usually progressive, so as to threaten life and to justify the use of a remedy attended by risk. This is exemplified in a man of forty, whose case was recently reported to the Clinical Society of London by Mr. Hulke, of the Middlesex Hospital. Three years previously, in Missouri, a Derringer pistol had exploded as the man was putting it in his right hand trowsers pocket, and a bullet had traversed the thigh, wounding both vein and artery at a point about six inches below Poupart's ligament. There was little bleeding at the time, and relief was ultimately sought some years afterwards because the limb was weak and painful, and its surface affected by eczema and ulcers. From the point of injury upwards, the femoral artery and vein were greatly dilated, and the risk in attempting

[1] The Practice of Surgery, etc.; London, 1876, vol. i. p. 435.

[2] Nélaton has the credit of pointing out the fact that, whilst the murmur of an ordinary aneurism can be heard only after the systolic impulse, and is therefore interrupted, the pulsatory thrill of an arterio-venous aneurism is continuous. It is intensified by the systolic impulse, but does not intermit. This circumstance should always arrest attention, as indicating the existence of venous communication. I have not verified the statement of systematic writers that, in varicose aneurism (*i. e.*, where a distinct tumor has formed), the interrupted bruit resulting from the passage of the blood in and out of the aneurismal tumor can be heard distinct from the continuous thrill caused by the opening into the vein. The "rasping bruit" is heard also in cirsoid aneurism, but everywhere equally; whilst in arterio-venous aneurism it is loudest at one spot, viz., near the point of communication. There is also less forcible pulsation in the artery below the point of communication in most instances where an artery opens directly into a vein; and a tendency to dilatation of arteries above.

to tie the former above and below the abnormal opening was considered too great. Compression, direct and indirect, was patiently tried and found useless, except in benefiting the eczema and ulcers. Ligature, as for simple aneurism, was seriously thought of, but deferred. Meanwhile the patient received so much relief by wearing an elastic laced stocking reaching from the foot to the groin, that he willingly accepted the advice to content himself with this palliative treatment.[1]

In a recent case, and in a young subject, the probability of a permanently weakened limb would possibly justify an operation as for a wounded artery, as in the cases of Spence and Annandale, of Edinburgh, and the use of an Esmarch's bandage would greatly facilitate such a proceeding. But in an old case, the number and size of the enlarged and tortuous vessels all carrying arterial blood, the enfeebled vitality of the limb, through habitually defective blood-supply, and the thinned walls of the arteries, unite to render all operative interference difficult, and, as regards gangrene and secondary hemorrhage, especially dangerous,[2] as pointed out by Breschet in 1838.[3]

As long ago as 1848 I sought to aid in establishing this point of practice. The late Valentine Mott tied the external iliac artery in a young man from Alabama, for an arterio-venous aneurism in the same locality as in the case just related, two years and a half after the gunshot wound by which it had been caused. The patient had complained of lack of power, and more or less pain in the limb, but mainly of the exaggerated pulsation and continuous vibratory thrill over the course of the vessels. After the operation the limb fell into gangrene at once, and the patient died on the sixth day. I had an opportunity of dissecting the parts, and found two small aneurismal tumors formed out of the adjacent tissues, besides a direct communication between the femoral artery and vein. Impressed by this grave reverse, I collected all the recorded cases within my reach in which arterio-venous aneurism of the lower extremity had been treated by ligature on the Hunterian plan, and found that gangrene, or secondary hemorrhage, had occurred in all of them. In twelve cases, the external iliac was tied in five, and gangrene followed in all; the common femoral in two, and gangrene followed in both; the femoral artery in five, and gangrene occurred in two of these cases, and hemorrhage in all.[4] Subsequently Norris deduced a similar result from the analysis of the cases of Hunterian operation for arterio-venous aneurism in his tables of collected cases of ligature of the femoral and external iliac arteries; and considering this result in connection with the clinical fact that arterio-venous aneurism in most instances tends to lose its progressive character and become stationary—causing only inconvenience, and not danger to life—this excellent surgeon recorded his opinion that sound surgery condemns a resort to operative measures in the treatment of such cases, "so

[1] Trans. Clin. Soc. London, vol. viii., 1875, p. 175. Similar cases of arterio-venous aneurism of indefinite duration, without material progress, must have presented themselves to most surgeons of experience. Norris quotes a case of Dupuytren's of twelve years' duration, and speaks of another he saw in Velpeau's wards in 1835, of twenty years' standing; and still another of "long continuance, which inconvenienced though it did not distress the patient."—Contributions to Practical Surgery, etc., Phila. 1873.

[2] Prof. Donald McLean, of Ann Arbor, dissected out and tied the popliteal artery and vein in an old case of arterio-venous aneurism (traumatic) above and below the point of communication, but lost his patient. (Private Communication, May 22, 1876.)

[3] Mémoires de l'Académie de Médecine de Paris.

[4] Cases of inguinal aneurism, with remarks. New York Journal of Medicine, vol. ii. (new series), 1848, p. 168.

long as the infirmity can be made at all bearable by the use of compresses, laced bandages, and other like measures."[1]

I regret that my time will allow me to say nothing of traumatic aneurism, especially as there are several most creditable American cases by which its treatment might be illustrated, in which in the neck, and even behind the ramus of the lower jaw—that most dangerous of all localities for a deep punctured wound—the tumor has been laid open and the vessel successfully tied above and below the wound in its walls. I may mention particularly the cases of Prof. Briggs, of Nashville, Tennessee,[2] of Prof. Donald McLean, of Ann Arbor, Michigan,[3] and also the more recent case of Dr. G. E. Frothingham of the same city.[4]

I am conscious that I have already taxed your patience too long with these imperfect notes; and I am equally aware that the extent of the subject has precluded the possibility, in such limited space, of reasoning up to very clearly defined conclusions. The treatment of aneurism at the present day clearly does not consist, as thirty years ago, in a choice between ligature and compression, but it involves judicial weighing of the claims of many remedial measures, the number of which is constantly increasing, and the selection of those which offer the best chances of safe and certain cure; and, where the chances of cure are uncertain, duty requires us to try those remedies which give the best promise of ameliorating symptoms and prolonging life. With the new methods of treatment at our command—to alleviate, if not always to cure—I will venture to assert that, whilst some of the operations on the great arteries sanctioned by distinguished names have failed to fulfil the hopes of their projectors—without any diminution, however, of the lustre of those names—Surgery is, nevertheless, richer in her aggregate resources; for there is no form of the disease which the well-trained surgeon of the present day can truly call incurable, or for which his art does not offer at least some hopeful resource.

Finally, I would submit the following conclusions for the consideration of the Section:—

I. Tufnell's treatment of aneurism by rest, position, and restricted diet offers a valuable resource in thoracic and abdominal aneurism.

II. It should always be tried in innominate, subclavian, subclavio-axillary, and iliac aneurisms, before resorting to measures attended by risk to life.

III. For aneurisms of the subclavian and iliac arteries, the Hunterian operation, with our present means of preventing secondary hemorrhage, is not justifiable.

IV. For reasons formally set forth by Holmes and Henry Lee, the "old operation" cannot properly be formally substituted for the Hunterian operation in these cases, but should be held in reserve for special cases.

V. It is the most safe and surgical resource in gluteal aneurism, if the circulation can be commanded by the hand in recto.

VI. The mode of cure by embolism, aimed at in the method of manipu-

[1] Contributions to Practical Surgery, Phila. 1873, p. 312.

[3] Peninsular Journal of Detroit.

[4] This case, which Prof. Gross in Amer. Journ. of Medical Sciences, April, 1876, p. 442, attributes to Prof. McLean, of the University of Michigan, I learn from this gentleman, belongs to Dr. Frothingham; Prof. McL. participated in it only as consulting surgeon.

lation, is a not unfrequent explanation of what is called spontaneous cure of aneurism.

VII. The value of Esmarch's bandage in the treatment of aneurism is probably not fully estimated.

VIII. In view of the promising features presented by the cases of Levis and Bryant, in which horse-hair was introduced into an aneurismal tumor, the repetition of this operation, or the substitution for the horse-hair of Lister's prepared catgut, or other animal substances, may be properly tried.

Discussion on Dr. Van Buren's Paper.

After the reading of the preceding paper, Mr. Jolliffe Tufnell, of Dublin, said:—I have brought with me from Dublin a number of alcoholic specimens, together with photographs and drawings, which show some of the cures which have occurred under the plan of treatment which I advocate in cases of internal aneurism. In following out the idea of the cure of aneurism by compression, I have found that it is not necessary to completely arrest the flow of blood through the sac, but that a simple diminution of the force of the circulation is all that is required. I have also found that the object can be attained by reducing the force and frequency of the heart's action, by placing the patient upon his back and by regulating the diet in such a way as to secure nutrition, and yet produce a decided lowering of vitality. A moment's calculation will show that if the number of pulsations be reduced from 86 to 56 in the minute, a gain will be secured of about 43,000 fewer pulsations in the day, a lessening of force which no one at first glance would fully realize. For the successful carrying out of this plan, certain conditions are necessary. Thus, (1) the aneurism must be upon the anterior wall of the artery, as those upon the posterior wall are frequently of the dissecting variety; (2) the sac must be entire, and (3) the blood must possess the proper fibrinating power. In those cases in which a hemorrhagic diathesis exists, and the patients bleed profusely from trivial injuries, the method is of course inapplicable. The difference in the force with which the blood is driven through the vessels is easily noticeable in one's own person, if the test is made between the reclining and the erect posture. I believe that the majority of cases of internal aneurism would recover if the patients would be content to lie in bed for three months and submit to the restrictions of diet, etc., which I have recommended.

In the treatment of aneurisms in the lower limbs, I have succeeded in effecting a cure by simply elevating the heel about six inches. I have, by this method, produced consolidation of a popliteal aneurism the size of a hen's egg, in twelve days, and the man is now doing full duty in the Royal Guards. I have here alcoholic specimens of several aneurisms cured by the plan which I have proposed: one is an aneurism of the thoracic aorta, in which the sac is filled with fibrinous layers; another, of the abdominal aorta, was cured in forty days, but soon afterward a dissecting aneurism formed lower down upon the vessel, and bursting, caused death, the first tumor being entirely solidified. In a third, in which the internal iliac artery was affected, both the aneurismal swelling and the degenerated artery became obliterated.

[The specimens referred to were then exhibited, and other cures were illustrated by drawings.]

Dr. J. H. Pooley, of Columbus, Ohio, said:—An opportunity is offered by one of the recent advances of surgery for us again to consider the old operation of laying open an aneurismal sac and tying both ends of the artery. This is the Esmarch bandage, which would not only act as a compressor, but would also give time to cut freely into the sac and leisurely hunt for the vessel

without fear of hemorrhage. In traumatic aneurisms, I believe that this is the most promising form of treatment, as these are practically wounded arteries.

Dr. Alfred C. Post, of New York, said:—Although the plan referred to by Dr. Pooley is undoubtedly a good one for aneurism of the traumatic variety, it would not be applicable to those of the idiopathic form. In the former case the walls of the vessel do not constitute the sac of the tumor, in the latter the vessel is diseased, and is likely to be in the same condition for some distance both above and below. In laying open the sac, in such a case, the artery itself would be opened and the ligature could not be properly applied within the sac. Even if the artery could be reached within the sac, this diseased condition of the coats would render secondary hemorrhage almost a matter of course.

Dr. George A. Otis, U. S. Army, said:—I understood Prof. Van Buren to refer to a case of ligation of the subclavian artery as a solitary example of shot-wound of the subclavian, in which the accident had not been followed by immediate death. The annals of surgery present other such cases, and several have been recently published. Prof. Billroth, in his Chirurgische Briefe zur Schusswunden, has cited several cases in which he was able to secure the right subclavian by ligature, after the above-mentioned injury, in the hospitals near Mannheim, in the Franco-Prussian War, 1870–71. I have endeavored to establish, in the fifth chapter of the Surgical History of the War of the Rebellion, that shot-wounds of the subclavian are not altogether beyond the resources of art, and have adduced five cases reported by reliable observers in which the fatal result after shot-injury of this vessel was delayed for several days, the artery having been secured in two instances by ligature. In one of the cases, the left subclavian was transfixed by a splinter from the shattered clavicle. I think that even in the presence of such supreme danger as is caused by an arterial lesion so near the heart, operative interference may sometimes be essayed.

Dr. John Ashhurst, Jr., of Philadelphia, said:—There is another set of cases in which the "old operation" may be properly preferred to the Hunterian method, and that is in certain cases in which the aneurism has suddenly become diffused. No doubt when this accident occurs in a case of popliteal aneurism, amputation is the safest mode of treatment, but in a case of femoral aneurism, laying open the sac and tying both ends of the artery may be advantageously substituted, as has been successfully done by Messrs. Birkett and Cooper Forster, of Guy's Hospital. Again, if an aneurism, in any locality, has ruptured externally, or has been accidentally opened through a mistake in diagnosis, the "old operation" may be the most available mode of treatment. Hemorrhage during the operation may be prevented by using, as suggested by Dr. Pooley, the Esmarch bandage, or, which I confess I think quite as good, the ordinary tourniquet. In axillary aneurism, the subclavian artery may be compressed over the first rib, through a preliminary incision, as advised by Mr. Syme; and in iliac or inguinal aneurism, bleeding may be prevented by using the aortic compressor, for the introduction of which surgeons are so much indebted to our President, Professor Lister.

I have lately had occasion to study the statistics of the operations of tying some of the larger arteries, and have been much impressed by the fact that as cases have accumulated the percentage of mortality has greatly increased. Thus, as regards the internal iliac artery, when the late Dr. George W. Norris published his classical paper, there were known but six[1] cases in which this

[1] Dr. Norris erroneously attributed a seventh (fatal) case to the late Dr. J. Kearney Rodgers, of New York; a mistake in which I confess to have followed him in my work on the "Principles and Practice of Surgery," in company with other systematic writers; and which has only recently been corrected by the laborious research of Dr. Otis, in the second volume of his Surgical History of the War.

vessel had been tied, and, of these six, four had ended in recovery; but while the whole number of recorded cases has since risen from six to twenty-five, the recoveries have risen but from four to seven, so that the death-rate has increased from only thirty-three per cent. to seventy-two per cent. Similarly, Dr. Norris collected sixteen cases of ligation of the common iliac artery, with eight recoveries and eight deaths, a mortality of fifty per cent.; while there are now recorded sixty-one cases, with only thirteen recoveries and forty-eight deaths, a mortality of seventy-nine per cent. These figures, it seems to me, speak very strongly in favor of bloodless methods of treatment, such as that which has been so beautifully illustrated to us to-day by the specimens shown by Mr. Tufnell, and which I, for one, am quite ready to agree with him in calling the "successful method of treating internal aneurisms."

Dr. S. Fleet Speir, of Brooklyn, said:—I would invite the attention of the Section to the "Artery Constrictor," which I have devised, and for which I claim the advantage of both effectiveness and safety. It consists of a mechanical arrangement for closing two jaws, one of which is curved so as to admit of its being passed beneath the artery, while the other forms a tongue, or male blade, and is forced down into a groove on the inner surface of the first. The advantage claimed for the groove is that it is so narrow as only to admit the external coat of the vessel along with the tongue, and that consequently the middle and inner coats must give way, and then retract and curl up so as to plug the artery with its own contents, and favor speedy coagulation. In this respect the "Constrictor" differs from Travers's instrument. I have used the "Artery Constrictor" successfully upon the femoral artery, in a case of popliteal aneurism, and also upon the common carotid in a case of supposed dilatation of the innominata, in which, however, it was found that the aorta was involved. In this case I tied the subclavian and constricted the carotid.

[Dr. Speir's instrument was then exhibited.]

The President, Mr. Lister, of Edinburgh, said:—I can testify to the value of Mr. Tufnell's method in many instances. One case I particularly recall which occurred in the practice of Mr. Syme, in which a patient, in whom it was proposed to tie the femoral artery for an aneurism of the popliteal, was placed in bed for a few days preparatory to the operation, and, although no particular attention was paid either to the lessening of the heart's action or to diet, yet, when he was brought to the operation table, the pulsation in the tumor was found to have entirely ceased. In regard to the distinction which has been drawn as relating to the traumatic or idiopathic nature of the affection, I do not think that this is a matter to be so much considered as the question which is the best and safest operation in the particular case, and the settlement of this question will depend more upon the position of the aneurism than upon its cause. In the case of popliteal aneurism, for instance, ligature of the femoral at the very apex of Scarpa's triangle, as practised by Mr. Syme, is a very successful operation, whether the tumor be traumatic or idiopathic in its origin; but ligation of the brachial for an enlargement of the vessel at the bend of the elbow, will probably fail to effect consolidation on account of the free anastomosis in this part. This intermingling of vessels is sometimes so intimate that occluding the brachial may not even destroy the radial pulse for one moment. In the arm, again, laying open the sac is attended with less danger than is the same operation in other portions of the body. Other important elements in deciding upon the form of operation are: The character of the tumor, whether fusiform or sacculated, and also the condition of the walls of the vessel. It should be remembered that the artery is just as likely to be diseased at a distance from the tumor as in its immediate neighborhood, since the location of an aneurism is usually the result of accident or some mechanical cause.

Should the Hunterian operation fail in aneurism at the elbow, I should certainly try the old operation.

With regard to the aortic compressor, or abdominal tourniquet, I would say

that, although I formerly supposed it to be original with myself, I afterwards found that it had been previously used by Professor Joseph Pancoast, of Philadelphia, who is entitled to whatever credit pertains to its introduction. As to the danger in the application of this tourniquet, referred to by Professor Van Buren, I think that it is due to the misapplication of the instrument. An inexperienced person, finding the artery beating below, may screw down the pad vigorously, while the difficulty really is that proper adjustment has not been effected. In such a case the intestine may easily suffer, but I guard against this by always placing a sponge beneath the pad.

I would like to say a word as to Mr. Holmes's allusion to the late Mr. Syme's advocacy of the ligature, as evidencing an "unaccountable prejudice" in its favor. The fact is that Mr. Syme lost but one case of femoral ligation out of forty, and that one from pyæmia. His other unsuccessful case was one in which a vascular tumor, not properly an aneurism, was treated by ligation, but proved fatal from hemorrhage. Mr. Syme always cleaned the artery very thoroughly before applying his ligature, and he tied the femoral below the apex of Scarpa's triangle, because, as he said, there are frequently very large branches given off from the femoral instead of from the profunda.

Professor Van Buren has said that one of the advantages of the antiseptic ligation of arteries is the avoidance of secondary hemorrhage. This is true, but there is also gained another important desideratum, namely, the diminished danger of diffuse inflammation. In ligation of the subclavian, if the operation were done thoroughly antiseptically, it would make no great difference even if the pleura should be opened, for the danger is not from such a puncture, but from suppuration, and when this is avoided the operation becomes a far safer one.

Dr. Ashhurst said:—I must say one word as to the history of the aortic compressor. I had the pleasure of being present when Professor Pancoast first used an abdominal tourniquet in amputation at the hip-joint (in 1859), and have myself since used, with satisfaction, the identical instrument, which is still extant in Philadelphia, in hip-joint amputation. But with all due regard to national pride as American surgeons, I do not think that we can afford to let the modesty of our President, Professor Lister, deprive him of the credit which is justly due him in this matter. The instrument which was used by Professor Pancoast was simply a large-sized Skey's tourniquet, and it is inferior to Professor Lister's ingenious clamp, or compressor, being more difficult of application, and of more complicated construction. Moreover, Professor Pancoast's use of the instrument was hardly known out of Philadelphia, and did not attract the attention of surgeons generally; so that although as a matter of fact he undoubtedly preceded Professor Lister in the employment of mechanical compression of the aorta, to the latter is as undoubtedly due the credit of having perfected the mechanical means of effecting such compression, and of bringing the method before the profession all over the world as a practical resource in surgery.

Mr. Tufnell said:—I would just mention that, many years ago, a similar instrument was devised by Mr. L'Estrange, of Dublin, for the compression treatment of aneurism, and is still preserved in the museum of the Royal College of Surgeons of Ireland.[1]

On motion, the conclusions of Dr. Van Buren's paper were adopted as expressing the opinion of the Section.

[1] [It may be added that in Mr. Birkett's and Mr. Forster's cases of diffused femoral aneurism, treated by "the old operation," the aorta was compressed by a tourniquet "recommended by Dr. Humble, many years ago, for compressing the abdominal aorta in cases of post-partum hemorrhage" (Trans. Clinical Society of London, vol. i. p. 38), so that the question of actual priority in the use of an aortic compressor probably cannot be settled.—Editor.]

THE PATHOLOGY AND TREATMENT OF MORBUS COXARIUS.

BY

LEWIS A. SAYRE, M.D.,

PROFESSOR OF ORTHOPÆDIC SURGERY AND OF FRACTURES AND DISLOCATIONS IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK, ETC.

Mr. President and Gentlemen:—

The time allotted me for discussing Morbus Coxarius, its causes, symptoms, and treatment, is so limited, that I can only briefly refer to the first two, and for more minute information must refer you to my published writings on this subject, where more definite and full information has been given; and I shall occupy a portion of the time with a practical illustration of the plan of treatment in each different stage of the disease, as being the best manner of conveying the largest amount of information in the time that has been allotted to me.

Morbus coxarius, or hip-disease, as it is generally called, is more frequently observed in childhood and early youth than at any other period of life, although it may occur in the infant or the adult. It is generally, if not always, the result of some direct injury to the joint involved, either (1) by a blow or concussion of the head of the femur against some portion of the acetabulum, producing an extravasation of blood in the network of vessels underneath the articular cartilage of one of these parts, and ending in caries and necrosis; (2) by some strain or overstretching of the joint, producing rupture more or less complete of the ligamentum teres, and its vessels and nerves, thus interfering with the nutrition of the head of the femur, and inducing necrosis; or (3) by excessive violence and over-exertion, producing free perspiration and synovial secretion, which is suddenly checked by an exposure to damp and cold, thus producing a synovitis which not unfrequently ends in suppuration.

The young infant is protected by the watchful mother or the careful nurse; and the adult has generally sufficient prudence to protect himself; but the reckless, romping, healthy child indulges in wild sports without discretion, and slight injuries are unnoticed until serious consequences have resulted, and often until so long a time has elapsed between the receipt of the injury and the development of symptoms sufficient to attract attention, that the cause of the difficulty is entirely forgotten, and the constitutional effects of long-continued irritation and suppuration are mistaken for the *cause* of the disease, instead of the *result*.

Until within a very few years, every author taught that the disease was necessarily connected with a strumous condition of the system, and could not exist without it, and that it was therefore necessarily of constitutional origin, and never occurred in the robust and healthy. This doctrine I believe to be incorrect; in fact, by a careful examination of my recorded notes of many hundreds of cases of morbus coxarius, I find that by far the larger number occur in children of perfect health, and born of healthy ancestry, and the simple reason is that children of this class are more active and daring, and therefore more exposed to accidents and in-

juries, than sickly strumous children who seldom have energy enough to expose themselves to any danger. But even the strumous constitution requires some local injury to the part itself, in order to develop the disease, and therefore I am inclined to regard the disease as almost always, if not always, of traumatic origin.

Of course the sickly strumous child, having less recuperative power and vital force to resist disease, will have it developed from a much less exciting cause than would be required to develop the same trouble in the healthy and robust; but even among the strumous I believe that, if sufficient care is taken in the investigation, the disease will nearly always be traced to some slight injury which was considered of so little importance as to pass unnoticed at the time, and that months afterwards, when the serious consequences of this slight injury have been fully developed in the well-recognized hip-disease, the universal belief in the doctrine of its constitutional origin has prevented the surgeon from examining for any other cause.

This has been the cause of the fatal error in the treatment of this disease; for, of course, as long as we believe that the disease depends upon constitutional taint, all our efforts will necessarily be directed towards correcting this constitutional poison or element. The result of all such treatment has been either death, after many months or years of suffering and exhaustive suppuration, or else recovery with more or less deformity, and with imperfect motion, or anchylosis more or less complete. Whereas, belief in its traumatic origin (no matter what the constitutional condition may be) will direct our treatment to the part involved, and, if the disease is early detected and properly treated, will result in the vast majority of cases in recovery with perfect motion and without deformity.

For convenience of description, I will divide the disease into three distinct stages, as each represents a different pathological condition of the parts involved; and, as the symptoms vary to a greater or less degree, so does the treatment applicable to each:—

I. The stage of irritation.

II. The stage of effusion.

III. The stage of rupture of the capsule, or perforation of the acetabulum.

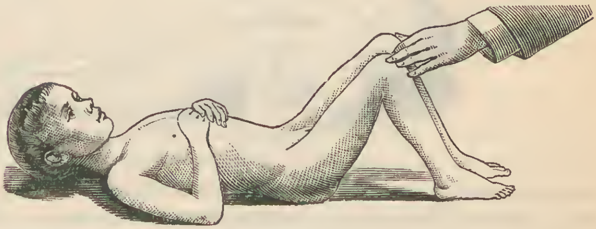
In the *first stage*, or the stage of *irritation*, before effusion has occurred within the joint, the symptoms are not well pronounced, and it often requires a very careful investigation in order to recognize the disease. Generally, the first thing noticed is that the child appears very slightly lame when he first gets out of bed in the morning, or when he first moves about after some hours of rest. This limping or halting gait is so slight as hardly to be observed, and, after a few minutes of exercise, may disappear altogether until the following day, or until after a few hours of rest, when it will again make its appearance on the first attempt at movement. The patient may sometimes complain of pain even in the early stage of the disease, but it is generally referred to the knee. Even in this early stage, however, if the child be properly examined, the disease can always be detected.

By stripping the child naked, and standing him on a table or on the floor, with the back towards you, the first thing noticed will be that the child bears his entire weight upon one limb, the other being slightly bent at the knee and hip, with its natis lower and more flattened than on the opposite side, while the corresponding gluteo-femoral crease is

lower than the other, is less distinct, and nearly obliterated at its outer angle. If you now let the child walk around the room, he may not limp at all, or not sufficiently to attract attention, in this early stage of the disease; but when you bring him back to the position as first described, and let him stand a moment or two, you will find that he invariably resumes the position of sustaining his whole weight upon the sound limb. (Fig. 1.)

Fig. 1.

Fig. 2.



You next lay the patient on his back upon a table, floor, or some other solid plane, covered only with a blanket, and lift his lower extremities until the entire spine touches the plane (Fig. 2), and twist the pelvis one way or the other until a line drawn from one anterior superior spinous process of the ilium to the other will be crossed at right angles by another line drawn from the centre of the sternum over the umbilicus to the centre of the symphysis pubis.

When the spinal column touches the plane, and the two lines above mentioned are at right angles to each other, the spinal column is slightly straighter than normal; but it and the pelvis are at right angles, and, if no disease exists within the hip-joint, the limbs can be brought down upon the plane, so that the popliteal spaces can be made to touch the latter without disturbing the relation of the lines described, and without lifting the spinous processes from the plane. If you therefore hold the suspected limb in your hand in such a manner as to keep the spinous processes on the plane while the other lines are at right angles with each other, you will observe that the well limb can be pressed down to the table so that the popliteal space will touch. (Fig. 3.) The diseased limb can be pressed down nearly to this position, but, before the popliteal space touches the plane, you will notice that the pelvis becomes tilted, making a curve in the lumbar vertebra, so that the hand can be passed between the child's back and the plane. (Fig. 4.) In flexing the limbs,

the well one can be completely flexed, so that the knee will touch the thorax; the diseased one cannot be flexed to this extent; and before the knee touches the thorax the pelvis becomes lifted from the plane. Abduction and external rotation may, possibly, at this early period, be

Fig. 3.

Fig. 4.

carried nearly to their normal extent without much pain, but adduction and internal rotation are much more limited. Pressing the head of the femur into the acetabulum, by concussion at the knee or pressure over the trochanter major, will give pain, providing the pressure is made so that the head of the femur shall sweep around all portions of the acetabulum, the pain being made manifest the moment the parts come in contact in which the disease exists. Extension, even though very slight, in the proper direction, gives instant relief from pain, while pressure causes it as instantly to return.

Atrophy of the muscles of the thigh, from tonic contraction caused by reflex irritation, will often be found even in the earliest stages of the disease, so that the measurement of the two limbs will often differ by from one-eighth to one-fourth, or even half an inch. Rigidity of the muscles is one of the earliest symptoms observed, and is always present until the disease is entirely arrested.

If the disease be detected in this early stage, and properly treated, I am satisfied, from an extensive experience, that the great majority of cases will entirely recover, with perfect motion and without deformity. If the disease be not detected at this stage, and properly treated, it progresses until effusion takes place within the joint; and, in order to accommodate this increasing effusion, the limb becomes more flexed, more abducted, and more everted, or outwardly rotated—to unfold, so to speak, the capsular ligament, thereby enabling it to accommodate itself to the increased amount of fluid within.

This is the *second stage* of the disease, or that of *effusion*. The adductor muscles become more rigid and contracted under the influence of reflex irritation; constant efforts are made to draw the thigh inward, but without avail, as it is impossible for the limb to yield to their tractile force, because the effusion within the capsule compels it to assume the position above described.

This stage of the disease is attended by the most acute and agonizing pain, the slightest attempt at motion, concussion, or compression causing

the most extreme torture; even the jarring of the bed, stamping upon the floor, the slamming of a door, or anything that causes the least movement of the bed upon which the little sufferer lies, may be followed by an increase of pain. At this period of the disease the attendant is frequently awakened at night by a sharp, shrill, agonizing shriek. The nurse runs to the child, and probably finds it asleep. She will have hardly left the bed before the same thing occurs again; and this is often repeated a number of times during a single night. The inflammation of the joint produces reflex contraction of the muscles, thereby adding to the pressure between the diseased surfaces of the bones, and promoting absorption of the same, as also the peculiar deformity connected with this disease. The muscles are kept in this state of constant contraction in order to prevent any motion in the joint; but this incessant, constant, unremitting effort so exhausts the patient that finally he falls into a moment's slumber, from sheer fatigue, when, the muscles being relaxed, the limb changes its position, thereby producing motion in the joint, and causing such instantaneous pain that the muscles instantly give a spasmodic contraction, followed by the piercing scream to which I have alluded.

Of course, at this period of the disease, it can hardly be mistaken for any other, or misunderstood; but upon stripping the child, and examining him as I have directed that he should be examined in the first stage, he will be found to present, both in the erect posture and in the recumbent position, precisely the same appearances as in the first stage, only in a more marked degree (Fig. 5), the chief differences being that the limb

Fig. 5.

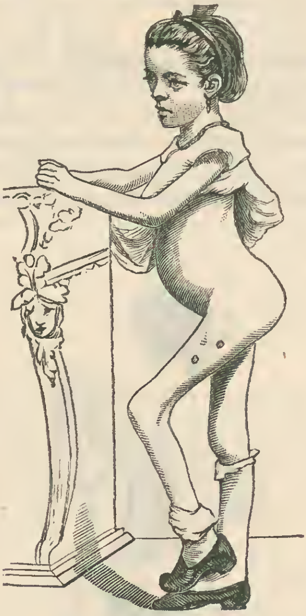
will be more flexed, *abducted*, and *everted*, or rotated outward, and the joint more fixed; in fact, any attempt to move the limb in this stage of the disease is futile, the entire pelvis rolling upon the opposite acetabu-

lum as if the diseased joint were positively anchylosed, though the supposed anchylosis is only apparent, being wholly due to muscular rigidity.

If the disease be not arrested at this stage, it goes on to ulceration of the capsule and effusion of its contents into the cellular tissue of the thigh, or else to perforation of the acetabulum and escape of the fluid into the pelvic cavity, pressing off the internal periosteum before it.

At this point begins the *third stage* of the disease; and as soon as the capsule is ruptured, or the acetabulum perforated, and the contents of the joint escape, either into the cellular tissue of the thigh, or into the pelvic cavity, the limb at once assumes an entirely different position. It now becomes *adducted*, *inverted*, and more straight at the knee; the pelvis on the diseased side becomes raised (whereas in the first and second stages, it was lower than on the sound side); and the limb is shorter. The gluteo-femoral crease is higher than upon the opposite side, whereas, in the previous stages it was lower, or entirely obliterated. (Fig. 6.)

Fig. 6.



If the rupture through the capsule is very large, so that the contents escape rapidly, this change in the position of the limb from that of the second to that of the third stage may take place in a single night; while if the opening is small and fissure-like, and the contents ooze out slowly, the change of form may not be completed for several days. In some cases, even when the capsule has ruptured, or the acetabulum been perforated, the limb will remain in the position of the second stage, owing to adhesions which may have formed, or to the head of the bone being locked in the opening through the acetabulum. The pain is greatly relieved upon this rupture of the capsule and escape of its contents, but the disease has only advanced one stage further in its progress.

It has been thought by many authors that, when this change takes place, the head of the femur is absolutely luxated from the acetabulum, and that this luxation is due alone to spontaneous muscular contraction. The

sudden change in the distortion, from flexion, abduction, and eversion, with elongation, to shortening, inversion, and adduction, has caused this belief in the occurrence of positive luxation, but in the sixty-three cases in which I have exsected the hip-joint, I have never seen luxation upon the dorsum of the ilium except in one single instance, and in that the dislocation was produced a few days before the operation by bending the limb in the effort to remove the patient from the bed, and was therefore due to the carelessness of the nurse, and not to spontaneous muscular contraction. The absorption of the head and neck of the femur, produced by constant pressure, diminishes its size, while the ilium being also pressed upon, becomes eroded and absorbed, thereby immensely increasing the size of the acetabulum. (Fig. 7.) But while this inter-

Fig. 7.

stitial absorption has been going on within the acetabulum, there has been at the same time periostitis upon its upper and outer borders, causing the formation of new osteophytes; and the capsular ligament, attached to these new deposits, has thus been gradually pushed upward and backward on the dorsum of the ilium, immensely increasing the size of the joint, but still retaining within its embrace what is left of the head and neck of the femur. It might therefore with propriety be called a displacement of the acetabulum, but not a luxation of the head of the thigh-bone.

This may appear a small point to cavil about, but accuracy in observation is essential for obtaining correct knowledge of the pathology of any disease, and unless our pathology is correct, our treatment will be necessarily empirical.

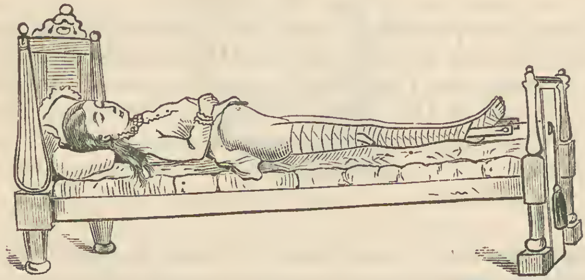
The pus or other fluid having now escaped from the capsule, the patient is greatly relieved from the pain, but the disease still progresses. Constant muscular contraction produces interstitial absorption of the head and neck of the femur, and of the acetabulum, and the pus, which has escaped into the cellular tissue, burrows in different directions, according to the position which the patient maintains, forming extensive abscesses which finally make their way to the surface. These sometimes open behind the trochanter, sometimes at a long distance from it, opening either upon the outer or inner side of the thigh, or on both; and even,

as I have seen in cases in which the acetabulum has been perforated, making their way between the internal periosteum and the ilium, and forming openings above the pubis; so that the third stage of hip-disease may be accompanied with external fistulous openings in various directions, and with very great exhaustion from extensive suppuration.

We are now prepared to study the *treatment* of morbus coxarius, which of course varies according to the stage in which we find the disease; and the reason that I have dwelt so particularly upon the diagnosis of the affection in its earlier stages, is because, as I have before stated, proper treatment at this time, in the great majority of cases, will be followed by perfectly satisfactory results.

In the *first stage* of the disease, if the symptoms of inflammation be very acute, and pain and tenderness very great, *absolute and perfect rest of the joint* is most essentially requisite. In the hearty and robust patient, in vigorous health, leeches or cups, or some other form of local depletion, may be necessary; ice bags, surrounding the joint, often afford the greatest possible relief, while in other instances hot fomentations, the exact opposite, will give the greatest ease. There is no rule with which I am acquainted, that will guide you in the application of heat and cold, except the feeling of the patient, and this can only be determined by a practical test. The remedy which gives the greatest relief, and is the most agreeable to the patient, is the one to employ. In addition to these local measures, extension (very slight, but continuous) *in the line of the deformity*, should be made by means of a weight and pulley, secured to the limb by strips of adhesive plaster, and a roller. The adhesive strips should always extend above the knee, to avoid traction upon this articulation. The pulley should be attached in some manner to the bed, the foot of which should be elevated ten or twelve inches, so as to make the body act as a counter-extending force. (See Fig. 8.)

Fig. 8.



When the extension is first applied, the traction should be made in the line of the deformity, and the direction should be changed by slow degrees, day by day, until the limb is gradually brought into its natural position. It is sometimes necessary to apply a second extending power, at right angles to the limb, to remove the pressure of the head of the femur against the inner surface of the acetabulum. This is readily done by passing a handkerchief around the upper and inner part of the thigh, securing in its outer loop a cord to which is attached a weight playing over a pulley at the side of the bed.

If the bowels are constipated, cathartics as a matter of course are indi-

cated; and all the secretions and functions of the body must be carefully looked to and kept as nearly in a normal condition as possible.

This plan is to be pursued until the more acute symptoms have subsided; but as the disease is chronic in its nature, *time*, as well as *rest*, is a very important element in its treatment. And as long confinement in bed is injurious to the general health, we must contrive some mechanical appliance which will give the necessary amount of extension and counter-extension to relieve the joint from pressure, while at the same time it allows it to have free motion, and permits the patient to take exercise in the open air.

In some cases, when the disease is very acute, and the child very small, this is best effected by placing him in a wire cuirass (Fig. 9), which is a modi-

Fig. 9.

fication of Bonnet's "*grand appareil*," and which will be found very useful. When this instrument, or any other fixed apparatus, is employed, it is necessary that the patient should be taken from it very frequently; and all the joints should be carefully moved, lest too long-continued rest may terminate in anchylosis, not only of the joint diseased, but of all the other articulations thus permanently deprived of motion. I am aware that Dr. Thomas, of Liverpool, has denied this doctrine; but having seen the result in a number of cases, I must be pardoned if I insist upon placing more confidence in my own personal observations than in the theories of

any one. Perfect rest, too long continued, even of the diseased joint, is decidedly injurious, as there is danger of its resulting in anchylosis; hence the objection to plaster of Paris, or any other fixed apparatus, in the treatment of this affection. The disease is essentially *within* the joint, the capsular ligament not being involved; hence, all that is required is extension and counter-extension, just sufficient to prevent the diseased surfaces from coming in contact; while at the same time motion is permitted, to keep the capsular ligament and other parts not involved in a healthy condition, by allowing the free use of this their natural stimulus.

If the child is large enough to run about, and the thigh sufficiently long to give attachment to the adhesive plasters, then the short splint (Fig. 10) is altogether preferable. I have used this splint for many

Fig. 10.

years, and having tried all others, I find it altogether the best wherever it can be applied, as it allows free flexion at the knee, and is, therefore, more comfortable in the sitting posture. If the patient is ten or twelve years of age, and too heavy to bear the weight of the body upon the instrument without breaking it, or if too much tension is produced upon the skin by the adhesive plasters, then crutches will be necessary when the short instrument is used. If the child's thigh is too short, and he is too small, to receive a sufficient amount of extension by the use of the short splint, then the long splint, which I here show you (Fig. 11), is much to be preferred, and with it, if properly applied, the patient will be able to walk without the use of a crutch.

The short splint and its various modifications, together with the long splint with its abducting joint and rotating screw, and their mode of application, have already been so fully described (in my work on Diseases of the Joints), that I shall barely refer to them here.

The short splint (Fig. 12) consists of a curved cross-bar, surmounting the crest of the ilium or entire pelvis, well padded on its inner surface, and to its two extremities are fastened a perineal band or bands, for counter-extension, and on its outer surface a ball-and-socket joint, from which

runs an iron rod or bar down the outer side of the thigh to within about two inches of the lower end of the femur. This outer bar is divided into two sections, one running within the other, and gauged or controlled by a ratchet and key, which can make it longer or shorter. At the lower

Fig. 11.

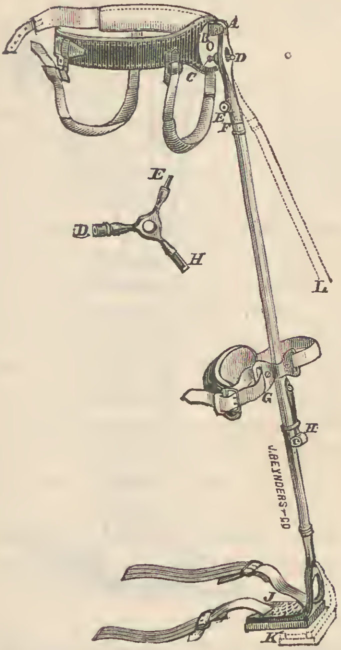


Fig. 12.

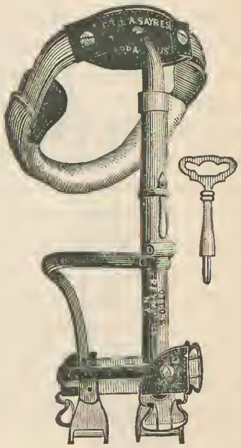

extremity of this outer bar is a projecting branch going around to the inner surface of the thigh to receive the attachments of the plaster, hereafter to be described. Both of the lower extremities terminate in cylindrical rollers, over which the tags of the plasters are attached to the two buckles placed at the lower ends of the instrument.

In applying the instrument, it is first necessary to have the adhesive straps to which it is to be fastened properly secured, and this is done as follows. When using the short splint, which is only worn during the day, night-extension is necessary, which is effected by means of weight and pulley: for this purpose a strip of adhesive plaster, to the lower end of which a stout piece of webbing is sewed, is placed on either side of the leg, extending from the malleoli to *above* the knee, in order to avoid traction on the lateral ligaments of the knee-joint; this is secured by a well-adjusted roller, leaving the pieces of webbing projecting for the attachment of the extending force. (Fig. 13.) Next, for the application of the instrument, triangular pieces of plaster, in which are cut several slits converging toward the apices of the pieces, are placed on both the outer and inner side of the thigh, first measuring with the instrument so that the tags which have been sewed to the apices of the plasters will exactly conform to the places of attachment upon its lower extremities. Having secured these with a roller, using care at the upper part of the thigh to reverse each alternate strip of the plasters in carrying round the

roller (Fig. 14), and with another turn taking in the other strips—braiding them in, basket-shaped—run the roller down the thigh again and sew.

Fig. 13.

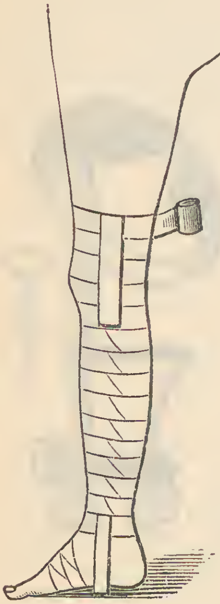

Fig. 14.

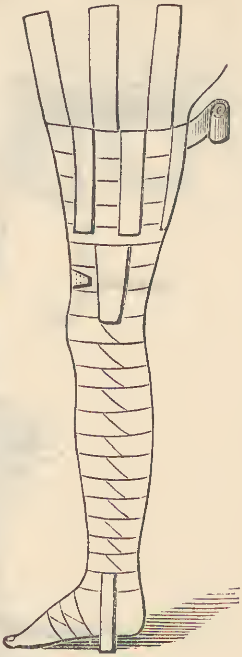


In applying the instrument, first buckle on the straps at the lower extremity of the femur. Then pass the strap under the femur to the buckle at the outer side of the instrument for the purpose of keeping it in place. We now pass the perineal band around the perineum, and buckle it snugly, but not too tightly. We next insert the key into the ratchet, and make gradual extension, until the patient is made perfectly easy, and until compression can be made upon the femur against the acetabulum without pain. It is sometimes necessary to employ two perineal bands, and then the cross-piece at the top nearly surrounds the pelvis.

If the disease has arrived at the *second stage* before we see it, and the effusion is very great, which will be indicated by the abduction, flexion, and eversion of the limb—sometimes even fluctuation can be detected—the patient must be kept in bed and the extension applied to the limb exactly in the line of the distortion, which will be in the line of flexion and abduction. This line of extension is to be changed day by day, by slight degrees, until the limb is brought as nearly as possible to the straight position. Blisters applied occasionally over the joint may hasten the absorption of this effusion. Firm strapping with adhesive plaster around the joint and compression with a sponge and roller may also be applied for the purpose of aiding absorption; of course, extension being used before this compression is employed. It is barely possible that the effusion may be so great as to paralyze the absorbents, and that no treatment will decrease the effusion. Under such circumstances aspiration of the joint is not only advisable, but the proper treatment, and

will be immediately followed by a restoration of the joint to its natural position.

When the limb has been brought to nearly its normal position, then the treatment by the short or long splint, according to circumstances, is the same as in the first stage of the disease, the plasters being re-adjusted as often as necessary. Good adhesive plaster (Maw's, of London, I have found to be the best), properly applied, will frequently remain in position from two to four months, seldom requiring removal oftener than once in six weeks or two months.

If the disease has gone to the *third stage*, capsule ruptured, abscesses formed and not yet opened, it is necessary to puncture these abscesses at various points where they are nearest the surface to prevent the pus from burrowing. The limb then being adducted, the extension, as a matter of course, must be exactly in the opposite direction from what it would have been in the second stage of the disease, and the limb gradually abducted until it is brought parallel with the other, when the splint, either long or short, is requisite, to be modified by the *abducting screw*, which I have been in the habit of using for many years with great advantage. In numerous instances, even when the disease has progressed to this stage, by the use of the splint the patient is enabled to improve the general health by out-door exercise, which frequently results in perfect recovery, and in some cases with a moderate degree of motion. The majority of the cases, however, that have arrived at this point before proper treatment has been adopted, are apt to recover with more or less complete anchylosis; in fact, anchylosis should be considered in this stage of the disease a very favorable termination.

The long splint (Fig. 11) which we sometimes have to use, differs from the short one, in the following particulars:—

In the first place, it extends the entire length of the limb, receiving the weight of the body at a cross-bar under the foot, and upon two perineal straps which are attached to an iron girdle which very nearly encircles the pelvis. Where the adduction is great and the joint fixed, it will be necessary also to apply the abducting screw, and in some cases, when the inversion is very great, a screw for the rotation of the foot outward is also necessary. The long bar, reaching from the pelvis to the bottom of the foot, is hollow, and has another bar running inside of it furnished with a ratchet and key, by which we make extension, and which is locked in the same way as in the short splint. The cross-bar at the bottom of the instrument is covered with leather to keep it from making a noise on the pavement while walking, and a strong leather strap is passed beneath two iron rods above this latter for the purpose of buckling on to the adhesive strap upon either side of the leg to make extension.

In applying it you take two strips of strong moleskin adhesive plaster, from two to four inches in width, according to the size of the patient, and the entire length of the limb, the upper extremity of the plaster being divided into strips for two or three inches. Strong webbing, an inch or two in length, with buckles, is sewed fast to the lower extremities of the plasters. These plasters are then placed on either side of the leg in such a manner as to leave the buckles a little above the ankle-joint, and secured by a snugly-adjusted roller, so applied as to leave the tags with buckles attached hanging loose, the roller being carried up over the knee, and as far up the thigh as can be done with convenience, when the upper split ends of the plasters are reversed and braided in with the roller as it

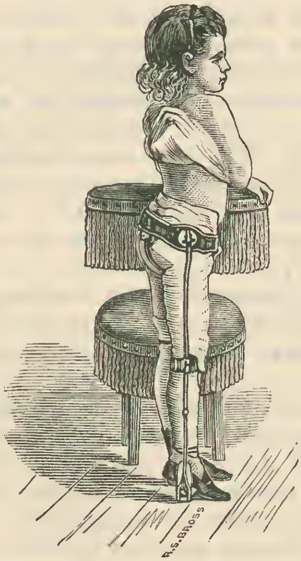
turns down the thigh, securing it smoothly. The stocking is next pulled up on the foot, and holes cut on either side for the buckles to pass through, and the shoe then applied, and corresponding holes cut through it for the same purpose.

The instrument is now placed on the outer side of the leg, with the cross-bar at the bottom brought in front of the heel of the shoe, and securely buckled to the tags above described. The pelvis-belt is next brought around the hips, and secured by the buckle upon the opposite side, and the perineal bands attached as firmly as need be. The knee-pad band is then slipped up or down until it is made to rest opposite the knee, where it is passed round the leg and buckled fast. Extension is now made by the key upon the ratchet until free compression is borne without pain. The abducting screw is then to be used, and daily turned, for the purpose of abducting the limb.

If the limb be strongly flexed, an additional power is applied at the posterior part of the instrument at the knee, running up the back of the thigh, and secured to the posterior portion of the pelvis-belt, and made tighter as occasion may require for the purpose of extending the limb. This latter strap should be always elastic, for the purpose of keeping up a constant tractile force, and at the same time allowing of flexion when the patient wishes to sit down. A fixed or leather strap, as used by Taylor, prevents any motion whatever at the hip, and simply anchyloses the joint.

By this means many cases that have gone to the third stage of the disease may in the course of time recover, with tolerably good form and a moderate degree of motion, without any further operative procedure. (Fig. 15.)

Fig. 15.



If, however, notwithstanding your treatment, the disease progresses, and suppuration increases, the joint becoming more and more impaired, showing a case of progressive caries, we then have no remedy except in *exsection*.

Nature's only way of curing these cases after they have arrived at this point is by the slow exfoliation of the carious bone, and, if this is limited in amount, she is often successful; but if involving the entire head and neck of the femur, with more or less of the acetabulum, as it frequently does, the process is a very tedious one, and the patients often succumb before nature completes the cure; and even in the most favorable cases healed by nature in this way, they have been left always with permanent deformity and imperfect motion—in fact, with a very much less useful limb than those which have been cured by exsection. I have now performed this operation sixty-three times, and can, therefore, speak with positive assurance upon the subject.

The operation is very simple, indeed, and in itself attended with almost no danger. The patient being anæsthetized and laid upon the well side, an incision is made from a point midway between the crest of the ilium and the top of the trochanter major, the knife carried firmly down to the ilium, and drawn with a single sweep downward and outward over the posterior edge of the trochanter major, and then curved forward and inward, making a crescent-shaped incision of some four to six inches in length, according to circumstances, and carried fairly down to the bone in its entire extent. The wound is then held open with spatulas, and a narrow firm-bladed bistoury is carried around and close to the femur just above the trochanter minor, and at right angles to the first incision, dividing only the periosteum, but in both directions, as far around the bone as can be reached, one-half or three-quarters of its circumference. By this circular division of the periosteum you avoid the danger of tearing it off from the femur below the point where section is to be made. If the first incision has not divided the periosteum completely, then carry your knife again through the first incision from the top of the trochanter major down to this cross-incision just described, pressing it firmly through the periosteum down to the bone. The periosteal elevator is then placed in these two triangles, and the periosteum peeled off from the trochanter major, carrying with it necessarily the muscular attachments to it. This can be very successfully done until you reach the digital fossa at the neck of the bone and behind the trochanter major, where the blade of the knife will be necessary to divide the tendinous insertions of the rotator muscles. The capsule being freely opened, the head of the bone will now be easily lifted from the acetabulum by strongly adducting the limb and depressing it, thereby tearing off the internal portion of the bone from its lining periosteum, when the finger can be glided around the bone, and with a finger or chain saw it may readily be removed below the trochanter major. By this means the periosteum will not be peeled off from the bone below the point of section with the saw, as is too often done by luxating the bone too forcibly.

If upon the first section it is found that the caries has extended still further down the femur, you can very easily separate it from its periosteal attachments, and whatever amount of bone is necessary can be removed in the same manner with the saw. Under no circumstances should bone forceps be used in the section of so large a bone. The trochanter major should always be removed, even if it is not diseased, as otherwise it would occlude the opening and prevent the escape of the discharge; and by peeling it from its periosteum, as I have before described, the attachments of the muscles are all left for future use.

When the head and neck have thus been removed, you have a fair opportunity to explore the acetabulum, and to remove all the carious or

necrosed bone by scraping and gouging. If the acetabulum be perforated, which I have frequently found to be the case, with a little care the necrosed bone can be chipped off down to the point at which the periosteum is attached. I have only in one instance found the internal periosteum perforated.

After washing the wound carefully with warm water, fill it with Peruvian balsam; a small plug of oakum should be inserted to the very bottom of the acetabulum, and left dependent from the wound. The upper and lower ends of the incision are then brought together by stitches, and if necessary adhesive plaster, and the patient placed in a wire cuirass (Fig. 9) with a window opposite the place of incision. As it is of the greatest importance that this dressing should be done with care, I will describe to you my mode of doing it.

The cuirass being properly prepared and well padded, the patient is laid in it so that the anus is opposite the opening, and free from any possibility of obstruction. The well leg is the first one to be dressed. By making it perfectly straight and screwing up the foot-rest until it is brought firmly against the heel of the patient, having a pad between the foot and the iron rest to absorb the perspiration, the instep is then well padded with cotton or a blanket, and a roller is carried firmly round it and the foot-rest, running up over the limb; but before going over the knee a piece of pasteboard, or leather, or several pieces of folded paper, are placed over the leg, knee, and thigh, and the roller carried firmly over this extemporized splint for the purpose of preventing the slightest bending of the knee, when the roller is carried up the entire length of the thigh, around the perineum and over the outer arm of the instrument, and several times back around the perineum, and then across the pelvis, by which means the well limb is made a firm counter-extending force.

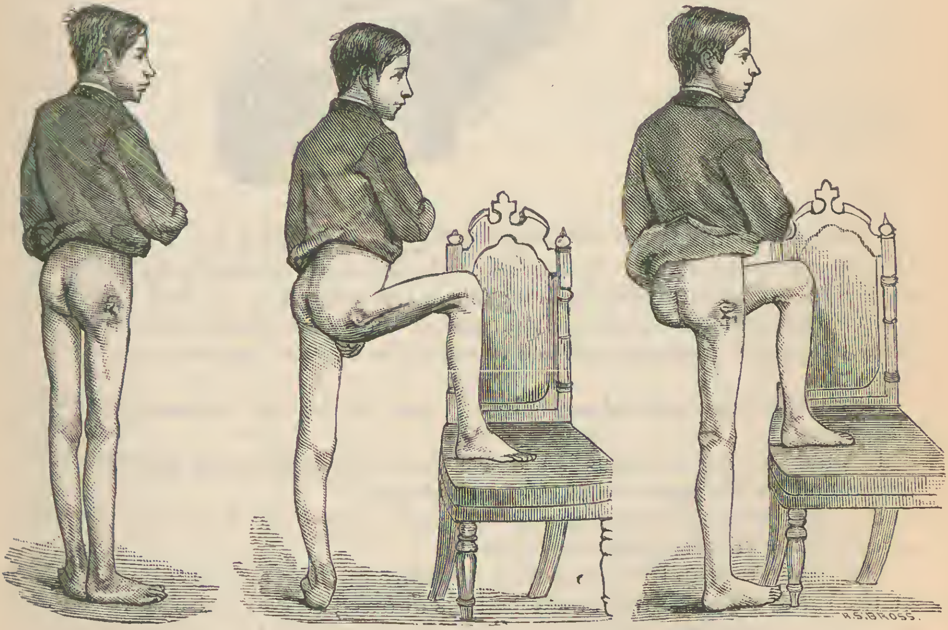
Two strips of adhesive plaster from two to four inches in width, according to the size of the patient, are then placed upon either side of the limb which has been operated upon, and secured with a nicely-adjusted roller over the foot and up the limb and thigh, as far as the abscesses on it or the wounds will permit, being careful to leave a sufficient length of the plasters, at the lower extremity, free for the purpose of applying them to the foot-rest when extension is made. The foot-rest is then screwed up to meet the heel of the shortened limb, and these strips of adhesive plaster are brought down around the foot-rest and securely fastened. The foot-rest is then extended by the screw, slowly and gradually, at times waiting a few moments for the muscles to yield, which have been so long contracted, until the limb is brought down to its full extent. It sometimes happens that, from long contraction of the adductors and the tensor vaginæ femoris, subcutaneous section of those tendons and fascia will be requisite before the limb can be brought to its proper position, even after the head of the femur has been removed. After the limb is brought into this position a roller is carried from the foot over its entire surface; a large wad of oakum is placed around the wound to absorb the discharge, and the roller is carried firmly over the wound, inner surface of the thigh, and around the pelvis. I place great stress upon this latter part of the dressing, as we thereby compress the tissues and prevent the burrowing of pus, the oakum, which has already been placed in the wound, allowing of free drainage, no matter how tightly the roller may have been applied.

Immediately after the patient is dressed in this way, and has recov-

ered from the anæsthetic, he is capable of being stood up against the wall, or riding out in a carriage or boat, and can take his daily exercise in this way. I have, in several instances, had patients removed a long distance, some miles, in fact, within an hour of the operation and without the slightest inconvenience or pain. This dressing will probably not require to be changed for from forty-eight to sixty hours, or until sufficient secretion has been formed to moisten the dressings, when the oaken plug can be removed without hemorrhage. If this dressing does not come away easily, warm water injections will readily float it out. The wound, made clean, is again filled with Peruvian balsam and dressed as before. After this it may require dressing once or twice a day, according to the amount of discharge, and the child should be removed from the entire instrument as often as it is requisite. The well leg should be removed from the instrument at least once a week, and free movements given to all the joints, ankle, knee, and hip, otherwise we may anchylose them, although they are not diseased. The wire cuirass should be used from a month to two months, or more, according to necessity, after which the patient can be put upon the long or short splint, and allowed to exercise, thereby increasing his prospects of perfect motion of the new joint.

In many of the cases which I have exsected, the motion has been as perfect and complete as in the normal joint, and in one case, that of Adolph Rousell (Figs. 16, 17, 18), the motion is greater in that joint than upon

Fig. 16. Fig. 17. Fig. 18.



the opposite side, and the limb less than a quarter of an inch shorter than the other, although it was sawn three inches below the top of the trochanter major, the head and neck having been entirely absorbed, and the acetabulum perforated. (Fig. 19. The four small pieces of bone are fragments from the acetabulum.) Only one of my exsections has recovered by anchylosis, and that was from neglect in the after-treatment, I

never having seen the patient after the operation for two years, and the gentleman who had it in charge having had no experience in the treatment of this class of cases. All the other patients that recovered have more or less good motion, and infinitely less deformity than those which have recovered by nature's process.

Fig. 19.

If the surgeon has not the opportunity of obtaining the wire cuirass, the after-treatment can be carried out just as successfully by applying extension and counter-extension, while the patient is in bed. But, of course, the patient loses the advantages of out-door exercise and fresh air, which in many instances will be found to be of vital importance.

From the foregoing observations, I am led to the following conclusions :—

I. That morbus coxarius is a disease most frequently met with in early childhood, or the age of reckless indifference.

II. That it is almost always of traumatic origin, and not necessarily connected with a vitiated constitution.

III. That rest and freedom from pressure of the parts involved, while at the same time the rest of the body is allowed free exercise in the open air, and a nutritious diet, is the best treatment that has yet been discovered for this disease.

IV. That if this plan of treatment is adopted in the early stages of this disease, the majority of cases will recover with nearly if not quite perfect motion, and without deformity.

V. That in the advanced second stage of the disease, when absorption of the effused fluid cannot be effected, then it is better to puncture or

aspirate the joint, and remove its contents, than to leave it to rupture by ulceration.

VI. That in the third stage of the disease, when the treatment recommended in this paper has been properly applied without satisfactory improvement, but progressive caries continues, then excision of the diseased bones is not only justifiable but in some cases absolutely necessary.

VII. That the operation of exsection of the hip is easily performed, and in itself attended with little or no danger.

VIII. That after exsection of the hip-joint, in cases of progressive caries, the recovery is much more rapid and certain, and infinitely more perfect as to form, motion, and the usefulness of the joint and limbs, than when left to the slow process of nature.

On motion, the Discussion on Dr. Sayre's paper was postponed until the next meeting of the Section, in order to afford the members an opportunity of witnessing a practical demonstration of the modes of treatment recommended, upon several patients who had been courteously placed by Dr. W. H. Pancoast at Dr. Sayre's disposal.

Accordingly, the next day, at 11 A. M., many members of the Section assembled in the surgical amphitheatre of the Philadelphia Hospital, when the first patient presented was a stout woman suffering from hip-disease in the *first* stage. She had been under treatment for some time in the hospital, and had been almost cured; but the splint had been removed too soon, and the disease had been re-developed. The night extension and short splint were reapplied by Professor Sayre in the manner described in his paper.

The second case exhibited was one in the first stage very far advanced. The patient presented the characteristic symptoms of this stage of the disease, but, as no instrument of a proper size was at hand, the case was referred for future treatment.

The third case presented was one in the stage of effusion, or the *second* stage. The patient was wholly unable to stand or bear the slightest pressure; weight extension in the line of deformity was applied.

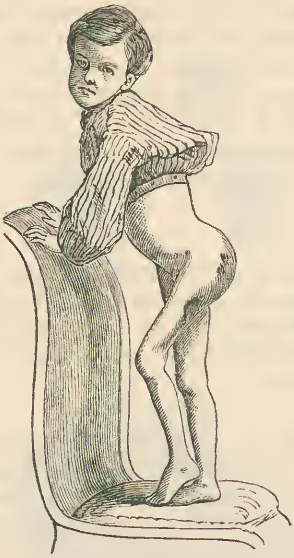
The fourth case was one in the *third* stage of the disease, and the following history was elicited: Thomas S., aged six, had been a healthy, active boy until about eighteen months ago, when he was knocked down and kicked in the region of the left hip. Soon after this he began to limp, but complained of no great amount of pain, that which he did experience being referred to the knee. During this time he was seen by several physicians, who did not discover any disease. He continued to become more and more lame, and at the end of six months a swelling made its appearance on the upper and outer part of the left thigh. He then began to complain of pain which was spasmodic in character, and always increased at night. The swelling was punctured, and, after poulticing for a few days, discharged a large quantity of pus. He has gradually lost flesh, and has become pale. This case was kindly furnished by Dr. J. M. Barton, clinical assistant to Professor Gross.

Present condition.—Extremely emaciated and anæmic; left thigh flexed, adducted across the middle of the opposite one, and fixed. (Fig. 20.) There is an opening in the outer part of the thigh, about the junction of the middle and upper thirds, which discharges considerably. The orifice has all the appearances of leading to dead bone, which is detected by the probe. A large abscess over the trochanter major is yet unopened.

Upon consultation with Mr. Adams, of London, Professor Lister, of Edinburgh, Professor Hueter, of Griefswald, Professor Hjort, of Christiania, Profes-

sor Hingston, of Montreal, Professor Post, of New York, and others, exsection of the head of the femur was decided upon, as affording the only chance of recovery.

Fig. 20.



While chloroform was administered by Dr. Sayre's son, Dr. Sayre said that his plan of using chloroform was entirely at variance with that taught in the books, and with the doctrine of most authorities, viz., that air must be inhaled with the anæsthetic. Air, he said, was the antidote to the anæsthetic, and as long as it was introduced anæsthesia would be prevented; he therefore carefully excluded all air not saturated with chloroform, and found that five, ten, fifteen, or twenty drops thus administered, according to the age of the patient, produced prompt anæsthesia, without that muscular resistance and contortion of the body which followed its administration mixed with air. If, by any possible contingency, this small quantity should produce dangerous or unpleasant symptoms, a few artificial respirations, effected by compressing the chest, would exhale the small quantity of poison, and thus avoid any fatal result. When chloroform was given in the usual way, *i. e.*, mixed with air, anæsthesia was not produced until a large quantity had been inhaled, in some cases many ounces, the patient during this time struggling violently; and the damage done to an inflamed joint by these struggles more than counterbalanced the good resulting from the anæsthetic. If, under these circumstances, failure of the heart or respiratory organs took place, the system was so saturated with the chloroform that resuscitation by artificial means was almost impossible.

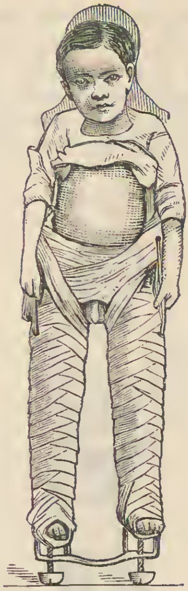
The administration of the drug in the present instance confirmed the correctness of Dr. Sayre's statements.

The operation was performed in the manner described in Dr. Sayre's paper, and the child placed in the wire cuirass (Fig. 21); great stress being laid upon the importance of careful dressing, after-treatment, and nursing. Dr. Sayre remarked, as he stood the child in the cuirass against the side of the amphitheatre, "now this child is ready for transportation."

Professor LISTER, of Edinburgh, being called upon by Professor Pancoast to address the company, spoke to the following effect:—We must all regard it as an extremely fortunate circumstance that Dr. Sayre has had at his disposal a series of cases so well adapted for illustrating his admirable diagnosis and

treatment of the various stages of hip-joint disease. As these subjects are to be brought before the Surgical Section of the Congress this afternoon, it is

Fig. 21.



needless for me to allude to them in detail on the present occasion, but I cannot refrain from expressing the admiration which I feel, in common I am sure with all present, at the mode of execution and the immediate results of the excision of the hip-joint which we have just witnessed. Dr. Sayre, indeed, has made no attempt at display, and he emphatically endorsed a remark of mine that the days of such exhibitions in surgery were over. For when pain and shock are prevented by anæsthetics, and when all loss of blood is avoided, whether by the use of a tourniquet, or, as in this instance, by the skilful manner in which the incisions are planned and carried out, mere rapidity of operating becomes a matter of absolute indifference, except that the work is probably somewhat better done if a little more time is spent upon it. Nevertheless, gentlemen, we have seen an extremely skilful performance, not only as regards the operation, but also in the application of the highly ingenious apparatus used for the after-treatment. The manner in which the sound leg, firmly fixed upon the cuirass, is made to serve as a perfectly efficient means of counter-extension, is indeed beautiful; and to see that boy who was but a few minutes ago a miserable crouching object, and on whom a capital operation has since been performed, standing erect before us upon this apparatus, with a smiling countenance, is as astonishing as it is delightful.

I feel that this demonstration would of itself have been a sufficient reward for my voyage across the Atlantic, and I beg you to join with me in a cordial vote of thanks to Dr. Sayre.

Professor Lister's suggestion was instantly seconded, and a resolution of thanks to Dr. Sayre unanimously adopted.

The following notes of the subsequent history of this case are furnished by Dr. D. J. Holland, Resident Physician at the Philadelphia Hospital:—There was not the least untoward symptom following the operation. The patient was given the pyrophosphate of iron and iodide of potassium, in small doses, three times daily, and for the first few nights a few drops of laudanum, as an ano-

dyne, though there was comparatively little pain. The limb was dressed every day, and a new tent placed in the wound; after the first month, passive motion was instituted. The patient's appetite gradually increased, and at no time had he any fever. His condition was excellent throughout, and within six weeks the wound had closed by granulation.

Two months after the operation, the patient was exhibited before the class at Bellevue Hospital as the most successful case upon record. There was at this time good motion. The cuirass was now removed, and Dr. Sayre's long splint substituted. Within a week the child became accustomed to the splint, and could walk without any exertion, and there was almost no shortening. He was discharged from the hospital, wearing the splint, November 11, 1876. (Fig. 22).

Fig. 22.

The following note has been received from Dr. J. M. Barton, under whose care the patient came again after his discharge from the hospital:—

Professor SAYRE:

Dear Sir:—I examined the boy Shields to-day, and found that there was five-eighths of an inch shortening; that the small of the back and the popliteal space readily came in contact at the same time with the hard table on which he was lying; that the foot could be raised eighteen inches before the pelvis moved; and that the limb readily passed a few degrees to each side of an imaginary line at right angles to a line connecting the anterior superior spinous processes, so that the boy could quite readily bring his limbs parallel, though he makes much more extended motion than that by moving his pelvis.

All the above motions, as well as pressure sufficient to move the boy upon the table, were totally painless. The limb rotated well; and the foot could be made to touch the table by its external edge, the boy lying upon his back, and could be rotated inwardly enough to touch the opposite foot.

There was about one fluidrachm of discharge in the twenty-four hours, and the boy's general health was excellent, and his appetite ravenous.

Respectfully,

J. M. BARTON,

201 S. Eleventh Street, Philadelphia.

Jan. 18, 1877.

Discussion on Dr. Sayre's Paper.

At the next meeting of the Section, the President having announced that the discussion of Dr. Sayre's paper was in order, Dr. Alfred C. Post, of New York, said:—In regard to the danger which attends excision of the upper extremity of the femur, I would say that the operation in early childhood is comparatively free from risk, but at later periods of life a very considerable proportion of fatal cases has occurred. Yet in many cases the danger of the operation is less than the danger of leaving the disease to pursue its own course. Even in some instances in which the operation is not necessary for the preservation of life, yet, if the case be allowed to go on to a natural cure, after having reached an advanced stage, such an amount of deformity will result as will render the limb an encumbrance, and in these cases the operation is of very great benefit to the patient.

Dr. S. D. Gross, of Philadelphia, said:—I came here this afternoon simply as a listener, but it strikes me that the second conclusion of Dr. Sayre's paper is entirely at variance with the received opinions of the profession, or at all events with my own experience. Many cases of coxalgia, according to my observations, have been cases in which it was impossible to trace as a cause anything like an injury. I have given special attention for many years to these cases of coxalgia: I have inquired "has the child received any injury—a blow, or a fall, or a contusion, or anything of the kind?" and in the great majority of instances the answer has been "no." I am quite certain that the majority of my cases—and they have been very numerous—have been of this character. That the disease may be developed or excited under the influence of traumatic causes is unquestionable; but I maintain that in the great majority of instances the affection is of spontaneous origin, and that it is not necessary for a blow, or a fall, or any such injury to produce the disease. This is my experience. In regard to the conclusion that it is not necessarily connected with a vitiated constitution, my teaching has certainly been greatly at fault if I err in this respect; I maintain, as the result of my dissections, that this affection cannot occur in a child or in any person whose constitution is not in a state of degradation, or who is not laboring under some constitutional taint. I believe that it is impossible for a person to contract consumption without a predisposition to it. So, in relation to hip-joint disease, consider, if you please, the nature of the suppuration which occurs in coxalgia. The surgeon finds an abscess, and puts his knife into the part; what is the character of the matter that issues? Manifestly the same kind of matter that is expectorated by a patient laboring under pulmonary consumption. This is beyond all question. I have never seen any other kind of matter escape.

This, I think, settles the question that the affection occurs naturally in persons predisposed to such diseases. It cannot arise in persons healthy in other respects. There must be a constitutional vice as a predisposing cause. The body must be in a state of debility or feebleness. This is my belief, nay, my solemn conviction. This degraded state of the system may arise from hereditary predisposition; the parent may have had scrofulous disease of the neck or spine, or some syphilitic taint; the predisposition has been transmitted, and the system has become degraded in consequence of the transmitted taint. The child has hip-joint disease, just as in other circumstances it might have had disease of the lungs, or tubercular phthisis, or disease of the spine. Indeed, we not unfrequently find more than one of these affections coexisting in different parts of the body.

The hip is affected in any particular case, simply because it is a weak point. The child may have taken cold, and the disease fixes itself in that locality. It might have fixed itself in the ankle-joint, or in the spine. The child may have received a blow, or a fall, or what not, but I maintain that that part is in a state of predisposition at the time when this takes place. I maintain that it is im-

possible for a child, born of healthy parents, well nourished, well taken care of, unless there is a previous predisposition or some degradation of the constitution, to have coxalgia, pulmonary consumption, or diseased spine.

Dr. Henry Fraser Campbell, of Augusta, Georgia, said:—In regard to the explanation of Dr. Gross, as to why the child has hip-joint disease instead of lung disease, I would say that scrofulous affections are developed in various forms at different ages. I agree that this disease is frequently produced by traumatic causes; I might go further and say that most cases which I have seen have been the result of some fall from the bed, or some carelessness of the nurse, or some twist of the child's limb or joint. But the same fall or twist, or the same carelessness, would not produce such a result in a healthy child, without any disposition to scrofula—in a child that had no syphilitic parentage. I recall one case in a very scrofulous child, in which an ordinary fracture of the arm resulted in the exfoliation of the entire bone. But this never would have occurred had that child not been of a scrofulous constitution. I believe that coxalgia may be one manifestation of scrofula, in childhood, just as at a later period of life tuberculosis of the lungs is another manifestation of the same general vice.

Dr. Wm. H. Hingston, of Montreal, said:—I formerly believed that scrofula or struma had everything to do with common coxalgia, but of late years I have come to think that it has little to do with that affection. Some years ago, in reading the papers of Dr. Sayre, Dr. Bauer, and others, I asked myself whether I was not in error in regard to the constitutional nature of this disease, and whether we were never wrong as to its treatment. In the large hospital at Montreal, the largest in Canada, to which I was surgeon for fifteen or sixteen years, I collected a number of cases which I published a few years ago—twenty-nine cases I think—and of those twenty-nine cases, I believe I could trace twenty-six to traumatic injury. And the treatment to which we have resorted is I think conclusive upon this point, differing as it does so much from the treatment formerly adopted. Without any constitutional treatment whatever, local measures suffice in a great number of cases. Again, we often see one child, out of half a dozen, having morbus coxarius, while the other children of the same father and mother are not affected with the disease. Now, is it the most sickly one that is affected? Not at all. In four cases out of five it is the healthiest child of the whole family. The child has a predisposition to the disease, but it is a predisposition to climb and to fall about. The sickly child rarely has hip-disease. I believe also that the affection is more common among boys than among girls, because they climb more; and it is more common also at that period at which children are cut loose from their mother's apron-strings, and are allowed to run about. As soon as they acquire sufficient intelligence to take care of themselves, the disease becomes rare; it is only in the period between infancy and adolescence that it is frequent.

Dr. E. M. Moore, of Rochester, said:—Like Dr. Gross, I have often asked whether or not there has been any injury, and I have largely failed to find any recollection of such an occurrence to which the disease might be attributed. But then we all know that these little bodies are constantly tumbling around, falling and straining themselves, and I have asked myself how is it that this particular joint, and no other joint, should be the one affected? It seems to me that the explanation of the fact has not yet been given. In the hip-joint we have a surface, small as compared with the ankle-joint, and very little larger than the shoulder or elbow-joint; and yet at this particular point in the body we have an immense mass of muscles surrounding the whole, and these huge muscles take hold of the bone whenever there is an injury inflicted, as they do in any other locality. So we have a reflex action set up in these cases, these muscles taking a sort of tetanic hold, night and day, to steady the joint. Why? Because nature is determined to secure rest, which is the cardinal cure of everything. So these muscles hold the bone up, and the surface is so pressed upon that whenever there is the slightest degree of inflammation, it must continue. Day by day

it will increase, while the child has forgotten the fall, until perhaps a deep-seated abscess is formed in the tissues. Dr. Gross asked whether we ever saw anything not like a scrofulous discharge from these abscesses? I answer, No; and the reason is that they are chronic abscesses, but there may not be the slightest evidence of scrofulous disease. In the same way we were formerly taught that Pott's disease originated from scrofula, but I have seen it traced directly to falls in cases in which no scrofula could be found for three or four generations backward. Again, we are told that these diseases originate from a deposit of tubercle, and the mere fact of finding tuberculous disease in connection with these affections is received as affording proof of their origin. But the connection may be reversed. It is what our medical friends are every day coming more and more to do. If there is no consumption but such as comes from hereditary taint, I ask why men who pick mill-stones never live above forty years. They do not expect a longer duration of life. I had one man, with a family dependent upon him, to tell me that he did not expect to live beyond forty years, but he was more fortunate; he lived to forty-five years, and then died of consumption. The grinders of needles and axes die of consumption. But is it of hereditary taint? It is because the particles of steel get into their lungs, and then produce chronic inflammation. These facts force themselves upon us. We all appreciate and understand perfectly well the force of hereditary taint, but it is unsafe to say that such is always the cause of tuberculous disease. I have myself become thoroughly convinced that a large number of cases of consumption can be traced to disease of cancellated bone. I recall one case of a young man of nineteen years who had inflammation of the tarsus, and a year afterwards presented evidences of tuberculous disease. I could not with the utmost care trace any consumption in that man's family. I am firmly convinced that a large number of cases of Pott's disease, which are followed by consumption, come from inflammation of the bone, and not from hereditary taint; because a large number of cases of the same affection which are cured can be traced to injury.

Dr. George Cupples, of San Antonio, Texas, said:—In regard to the question, why the hip-joint is more often affected than any other, I would say that perhaps a physiological fact may throw some light on the subject; this is the circumstance that the long bone of the body, the femur, is the last to be completely ossified.

Dr. T. G. Richardson, of New Orleans, said:—I would like the positive advocates of the local origin of coxalgia to explain why a severe injury in an adult is never followed by hip-disease. You cannot mention a case of the kind which has been followed by this affection. Then, too, I deny that the age of childhood, or the age of carelessness, is the age at which the hip-joint is most liable to injury, as is shown by the fact that we seldom or never have dislocation of this joint in childhood. Then, again, I call on those who maintain that coxalgia originates from traumatic causes to explain why it is that in cases of congenital dislocation of the femur we sometimes find hip-disease.

Mr. William Adams, of London, said:—I am satisfied that, in a large proportion of cases, it will be found that the exciting cause of hip-disease has been some slight injury; yet years of practice have taught me that there are cases in which the disease occurs without any injury. We used to be taught that hip-joint disease often originated as a bone disease, but my own belief is that it is usually the result of a ligamentous lesion. We have very few post-mortem examinations of cases in the first stage of hip-disease to refer to, but, in those which are reported, we find that an inflammatory condition of the ligamentum teres and a slight exudation into the synovial membrane were noticed;[1] and I believe that, in seeking the cause of the

[1] [See report of post-mortem examinations, made by Aston Key and by Mr. Adams himself, in Chelius's System of Surgery, edited by South and Norris, Philadelphia, 1847, vol. i. p. 290.—Editor.]

affection, we may look to an injury or wound of the round ligament, as from some strain, or twist, or jump, when the muscles of the child are in a relaxed condition. The injury, however slight, causes subsequent inflammation, the extent of the disease depending much on the constitutional condition of the patient. This inflammation may lead on to secondary bone disease, or, in other cases, and in particular states of the constitution, we may have primary bone disease.

Dr. D. Hayes Agnew, of Philadelphia, said:—It is important in discussing this subject to understand what we mean by the term traumatic injury, as preliminary to the whole question. Now, if it is necessary that a joint should have a powerful twist, or wrench, or that a blow should be inflicted upon it, or that the patient should be projected from some height—that is one thing; but, if it is meant that a child by jumping down, for instance, two or three steps, or by tripping on the floor in walking over a carpet, can in such a way receive traumatic injury—that is another thing. My impression in regard to hip-joint disease is this: It is impossible to follow a child in all its movements. Most of the time the child is out of the notice of its mother, in the care of nurses, many of whom are exceedingly careless. The child may receive a great many slight injuries which may yet be quite sufficient to produce such a contusion or such an irritation of the joint as, in a child predisposed (for I must confess that there is after all a predisposition, which may remain latent if the child be kept absolutely at rest), may kindle up the slumbering elements and bring on the disease. I see a great many of these cases, and I must say that I usually find it not difficult to trace behind all a constitutional predisposition. In the family, perhaps, one child may have phthisis, and another enlarged glands, and another hip-joint disease, and another knee-joint disease. But, in most cases, the immediate cause of the disease is some external injury of the joint.

Dr. Sayre said:—Both Dr. Gross and Dr. Campbell agree that some little injury may produce the disease. That is all that I claim; I do not assert that it is necessary for a child to be run over by a railroad car. If coxalgia is constitutional, I would ask why it is that, having recovered from hip-joint disease, the patient becomes perfectly well, and sound, and hearty? why is it that simply having hip-joint disease cures the constitutional taint?

Dr. Gross said:—The difference between Dr. Sayre and myself seems to be simply this: He says that hip-disease is almost always of traumatic origin, and not necessarily connected with a vitiated constitution. I, and those who think with me, do not deny that injury may excite the disease; on the contrary, we confess that it frequently does so; but we maintain that the disease is always necessarily connected with a vitiated condition of the system.

Dr. J. A. Grant, of Ottawa, said:—I must acknowledge that for many years I entertained similar opinions to those now expressed by Dr. Gross; but in one or two cases observed during the last few years, in the hospital at Ottawa, where I see many cases of hip-disease, I have been forced to a different conclusion. One case came under my observation about three years ago, which I investigated most closely, and in which I failed to trace the slightest predisposition of a scrofulous character, either in the boy, or in either of his parents, or in any of his ancestors. In another case that came under my notice, the disease arose purely from irritation or excitement in the joint, entirely independent of scrofulous complication. We must acknowledge, of course, that persons laboring under a scrofulous taint are much more liable to irritation, and to the development of this disease, than others; but we must also acknowledge, from the peculiar construction of the hip-joint, that it is one extremely susceptible to irritation, whether in a scrofulous constitution or in a constitution not of scrofulous character. I am of those who adhere to the view that we may have coxalgia occurring in an individual entirely independently of scrofulous taint.

Dr. J. H. Pooley, of Columbus, Ohio, said:—I will go further than Dr. Sayre's proposition, and say that I believe the disease is not only not necessarily connected with a strumous diathesis, but never connected with it except by the accident of coexistence. What is scrofula? Take all the gentlemen in this room, one by one, and make each man give his description of scrofula, and you will have as many separate descriptions as there are separate describers. We hear a great deal about scrofula, and hardly know what we mean. I not only endorse the proposition of Dr. Sayre, but I would have framed it in stronger language.

Dr. Hunter McGuire, of Richmond, Va., said:—I think I can reconcile in one or two words the different views expressed in regard to the occurrence of scrofulous pus in hip-joint disease. I cannot believe that anybody here ever saw any other kind of pus in coxalgia than scrofulous pus, but it does not necessarily follow that coxalgia is of strumous origin. I was taught five and twenty years ago, and I think I have profited by the teaching since, that scrofula resulted very frequently from pain or irritation, or from the privations of life, such as insufficiency of food and clothing; so that, if a little child gets a fall, rapid coxalgia may follow, and then, in consequence of the pain and loss of appetite, struma may be developed, and there will then be scrofulous pus.

Dr. John T. Carpenter, of Pottsville, Pa., said:—The point at issue, it seems to me, is the local origin of constitutional diseases, upon which Professor Niemeyer has laid so much stress. I published a paper recently, in the Transactions of the Pennsylvania State Medical Society, in regard to the diseases of miners. Miners are subject to phthisis, and rarely live over 45 years. That disease, which we always believed to be constitutional, is caused by nothing but the inhalation of coal dust. We find solid carbon in the patients' lungs. The men die, and the old women live in the villages. Now, if their sons leave the mines and go into the agricultural districts, they live as long as other people. Here is a local origin of constitutional disease, and so it is with coxalgia. Every one of us knows that the first sign of constitutional disease in cases of coxalgia is an irritative fever, and thereafter sinuses form, and there is a discharge of pus, and phthisis may follow. The struma does not exist in the case until after long suffering and long disease. It is the consequence, and not the cause. Children whom I have treated by Dr. Sayre's method are now healthy and happy, and have never had any phthisis, or scrofula, or anything of that kind.

Dr. William Brodie, of Detroit, said:—Some years ago, when Dr. Sayre's views were first promulgated, I had occasion to see a great many cases of this disease in Detroit, and, with my friend Dr. Pitcher, had occasion to examine a great many people who came in from the surrounding country, all supposing that they were going to be cured by the new method. Some of these patients died of their coxalgia, and some from other causes. A great many post-mortem examinations were made, and I came to the conclusion that the disease commenced in the cartilage, and that, when this was absorbed, the bone itself became affected. I noticed in these cases the presence of a low grade of constitution, as if the patients had suffered from typhus, or were in an impoverished condition from cold. We know that children frequently lie exposed at night, or get into water, or get chilled in other ways, and then the external surface is affected, and a low grade of inflammation produced, which results in suppuration of the cartilage. I have always considered hip disease as scrofulous in its nature, but I believe that it originates in inflammation of the cartilage.

The President, Mr. Joseph Lister, of Edinburgh, said:—The question whether this disease is or is not constitutional, must not be allowed to determine absolutely the treatment to be adopted. We must not say that because a disease is constitutional, that it is therefore hopeless to produce a permanent cure by treating it with local means. Take cancer, for example; that may be

in many cases constitutional, yet we know also of many cases of cancer which recover if operated upon early enough. There is a local manifestation of a hereditary taint, but if we take away the local manifestation, there may never be any other. This is the case also with struma. Glandular abscesses in the neck are strumous, and yet how many persons live to be healthy and sound after having these! It seems to me that if we have such a disease as struma at all, we have that disease in morbus coxarius. A child came to me in Glasgow to be treated for disease of the tarsus. He was treated with a long splint, and after a while, though still lying in bed, with the splint, several weeks afterwards, morbus coxarius showed itself. In that child there was a constitutional tendency which developed itself without traumatic cause. But I admit that traumatic causes are frequently operative, and we know the constant liability of children to be affected by traumatic causes.

Dr. Gross said:—Have you ever seen suppuration in disease of the hip-joint, in which there was not scrofulus pus?

Mr. Lister said:—I must confess that I have. In affections dependent upon strumous disease, there are great varieties of pus. The treatment which I have adopted has been, if there has been flexion of the limb, to extend it on a long splint, and keep the patient at rest. In the great majority of these cases in Edinburgh, perfect cures are obtained. In Glasgow, a considerable number of the cases are cured, but not so many as in Edinburgh. Then, again, in Manchester the number of cures is a minority. Now I believe the reason for this is that Edinburgh is a more healthy place than Glasgow, and that Manchester is a less healthy place than Glasgow.

Dr. Sayre said:—I can hardly find language to express my feelings of regret whenever I am compelled to differ in a professional point of view from my distinguished friend Dr. Gross. But we must not let personal friendship, or personal respect and veneration, guide us in the expression of our opinions upon points of science. It seems to be conceded that an injury is often the exciting cause of the disease. Now, with regard to the matter of predisposition, I say that the ordinary teaching has been erroneous, and I believe that the doctrine has led to bad results in treatment. If the disease is necessarily of constitutional origin, it cannot be cured by local means. You must get rid of the constitutional poison or taint. If it is of constitutional origin, the development of some constitutional cause, the treatment ought to be constitutional, to affect the blood and the whole body. What has been the result of the belief in the constitutional origin of hip-disease? The use of internal remedies to correct the constitutional taint, and of local applications to the parts that are simply irritating. Dr. Gross has referred to the character of the pus: I happened to be present at an autopsy in a case of hip-disease in Berlin, made by Prof. Virchow, where an examination was made of the lungs, and heart, and intestines. In the specimens taken from that case there was not a trace of tubercular matter to be found. It was simply a case of pure chronic coxalgia. The pus was not of the kind referred to by Dr. Gross. Had that case been carefully examined and properly treated, in my judgment it would not have terminated fatally. The trouble was a local one, and the constitutional effects of the local trouble were mistaken for its constitutional origin. Prof. Gross will remember seeing a little child whose hip I exsected in Brooklyn. If there ever was a strumous condition, that child's condition was certainly entitled to be called so. In fact the child was almost dead at the time of the operation. It had lain in an exhausted condition for five or six years, with continued suppuration, yet by removing the cause of the trouble, without any constitutional treatment, or medicine of any sort or kind except something to eat and fresh air, from being a dead child, the child is running about to-day in perfect health. I sent its picture as a Christmas present to Dr. Gross himself. Now, in reply to the remarks of Dr. Richardson about cases of congenital dislocation, I may say that congenital dislocation has never been seen, although it has been described by Dr. Carnochan and others, and I believe that I am justified

in saying that the term is a misnomer. There is no congenital dislocation, but an arrest of the development of the acetabulum, the bone having never been completed. It is a congenital *displacement*, from an arrest of development, but not a congenital *dislocation*. The dislocations that occur in the adult are immediately recognized and attended to, and after reduction the parts are kept at rest until all danger of inflammation has passed; whereas the slight injuries which cause hip disease in the child are overlooked, and attention is not called to them until, by continued irritation, inflammation has supervened; and the general health frequently becomes involved before the slight local injury is recognized. Moreover, in the adult the head of the femur is much less vascular than in the child.

Dr. Hingston said:—We are told that hip-disease may originate from injuries to the cartilage and bone, and also from ruptures or injuries of the ligamentum teres. Now, I am wholly prepared to admit that in the first set of cases local treatment would probably suffice to effect a cure, but I wish to know if the same degree of probability applies also to cases originating in lesions of the ligamentum teres?

Dr. Sayre said:—I can answer that question by a practical illustration. Five or six years ago a case of coxalgia was brought to me by Dr. Jourdon for excision. There was an open abscess, which had gone through all the various stages, the disease having originated from a blow two and a half years before. At the time I saw the case the child was hardly in a condition in which it was deemed advisable to operate, and so I thought it better, in order to save the child, to get it in a better condition. In the mean time, to make the child as comfortable as possible, and put it in a condition for treatment, I brought it out of its surroundings, and got it out of doors to build it up a little. When the time came for the operation, the child was so much better that I concluded to give it a chance without excision. I made a free incision into the joint, and took away a comparatively small portion of the bone only. Repair took place; the child got entirely well; and ran around a year and a half without any splint, and with only slight deformity, and with a tolerable degree of motion. Some year and a half ago, through exposure, the child got into a very bad condition, and the physician in attendance informed Dr. Jourdon that it was going to die. The child did die, and I have the specimen. The head of the femur and the ligamentum teres have entirely disappeared; a new covering had been formed, of what I do not know, but it was smooth, hard, and cartilaginous. So that that child lived two or three years without any ligamentum teres at all.

Dr. Post said:—With regard to the necessity of resorting to excision, we all have known of advanced cases of the disease in which there has been a favorable result. I was called, two or three years ago, to see a patient in Jersey City. The knee was thrown up almost to the chin. It was impossible to place the child in a position even approximately straight, in consequence of the extreme pain which the effort gave him. He was almost ready to die from the constitutional disturbance attending the advanced stage of the disease. He was placed under the influence of ether, and the limb brought into as straight a position as possible. It was during cold weather, when there was a fire in the grate, and I put a poker in the fire, and made a thorough application of it behind the great trochanter. Improvement began from that time; and some time afterwards the child was brought to me free from deformity. Here was an entire recovery, and this case goes to show that excision is not always absolutely necessary.

Dr. Sayre said:—I have only advised the operation in cases in which the disease progresses in spite of proper treatment.

Mr. Lister said:—I think that a distinction between the stage of effusion, and the stage of suppuration, would be more in accordance with the general pathology of the subject. I believe the last stage of hip-joint disease is invariably the stage in which suppuration is present. Where effusion exists

without suppuration, a permanent cure may result by drawing off the fluid. If the case has gone on to the condition in which sinuses present themselves, I should be prepared to endorse the proposition that exeision is the proper treatment; but if there is suppuration without an external opening, I am bound to express my strong conviction in favor of merely opening the abseess. I know of numerous eases in which the abscesses have been treated antiseptieally, and in which the patients have recovered. Certainly in these eases the treatment had better results than if excision had been resorted to. I remember one patient, a healthy young woman in Glasgow, whose two limbs beeame exaetly alike, exeept that there was the mark of the small incision made in opening the abscess; and this result was a great deal better than if excision had been adopted.

Dr. HINGSTON said:—I wish to ask Dr. Sayre if he ean tell from the position of the sinuses, whether the aeetabulum or the head of the bone is diseased?

Dr. SAYRE said:—I eannot; the pus will, in either ease, gravitate in the easiest direction.

On motion, the conclusions of Dr. Sayre's paper, with the exception of the seeond, were adopted as expressing the opinion of the Section. With the seeond conclusion, the Seetion could not unanimously agree.

REPORT OF A CASE OF SUB-PERIOSTEAL EXCISION AND DISARTICULATION OF THE ENTIRE INFERIOR MAXILLARY BONE FOR PHOSPHORUS NECROSIS.

BY

JOHN W. S. GOULEY, M.D.,

PROFESSOR OF DISEASES OF THE GENITO-URINARY SYSTEM IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NEW YORK, SURGEON TO BELLEVUE HOSPITAL, ETC.

THE record of the case I have the honor of presenting was intended to be incorporated in a paper on extirpation of the entire inferior maxillary bone, which I have in course of preparation, and in which I am desirous of including as many as possible of the illustrative cases contributed by surgeons of different parts of the United States and of foreign countries. I venture to report it now in order to recall attention to the subject, and thereby elicit information regarding cases, the notes of which I have not as yet been able to obtain, and also to gain access to unpublished cases.

The following is a list of names of surgeons whose cases have appeared in divers journals and surgical works, or have been communicated to me by the operators. The operations were done for tumors, as well as for necrosis; some of them were intra-buccal, but the majority were by external incision, at one or at two sittings, by one or, as in three instances, by two different surgeons at a considerable interval of time.

Name of Operator.	Residence.	No. of Cases.
Valentine Mott,	New York,	1
John G. Perry,	England,	1
James Syme,	Edinburgh,	1
Signoroni,	Padua,	1
J. F. Heyfelder,	St. Petersburgh,	3

Dr. Blackman (American Journal of Medical Sciences, October, 1856) mentions Walther, of Bonn, Marsh, of Cincinnati, Hutton, of Dublin, Gauwesky, of Westphalia, Cusack, of Dublin, and Liston, of London, as having each once excised the entire inferior maxillary bone, but I have not as yet found the original accounts of their cases.[1]

The subjoined notes of my case embrace the principal points I am desirous of obtaining from surgeons whose cases have not been published.

Mary N——, aged nineteen, came to this country from Ireland when nine years old. At the age of thirteen she was employed in a lucifer-match factory, where she remained for more than two years. Within a few months after entering the factory she had a decayed right inferior molar tooth extracted, and resumed work on the following day. But this does not appear to have caused any trouble. A year and a half afterwards another inferior molar was removed, also from the right side, and as before she at once went to work. Very soon after this she was attacked with phlegmonous periostitis, accompanied by inordinate swelling, which rapidly extended and involved the whole jaw. The abscess opened spontaneously at a number of points along the base of the jaw, on both sides of the face, and also in the buccal cavity. She lost successively the molars of the right side and the two left incisors. The fetid pus which continually issued from these various fistulous openings was so profuse as to greatly drain her vital powers. Her appetite and strength soon failed; she became anæmic; and her condition was worsening so steadily that, at length, she applied for treatment to a surgeon who made an incision along the right ramus, and removed a sequestrum which afterwards proved to be the coronoid process. This operation was of little use, as only a very small part of the dead bone was removed.

I found the patient at St. Vincent's Hospital, early in March, 1864, still further reduced in strength by her great suffering and by the profuse discharge already referred to. The right side of the face was paralyzed from division of the facial nerve at the time the incision was made to remove the coronoid process. The jaw was extremely rigid and mastication impossible. For nearly a year the patient had lived entirely on fluid food, and with it always swallowed a considerable amount of pus. All the sinuses led to dead bone. She was much disfigured by an enormous under jaw, made up of an unusually large involucrum with the overlying soft parts greatly swollen. On consultation with my colleagues, I proposed to remove the whole of the involucrum, as well as its contents, by external incision, as it did not seem expedient to attempt to save such an unwieldy bony mass, and because it was believed that its extirpation would not only remedy the existing deformity and distress, but also greatly facilitate the ingestion of proper food. To this proposition they assented, and, on March 19, 1864, I proceeded to operate after the manner described below.

The patient having been etherized and placed on her back, with the head

[1] I shall be greatly indebted to those who will have the kindness to indicate to me in writing the operators whose names may have been omitted, and to furnish me with facts regarding such unpublished cases as may have come to their knowledge. Each case must be one of disarticulation of both condyles, and ablation of the whole body of the bone, whether done at one or more sittings, by one or more surgeons. Communications relating to the information solicited may be addressed to 311 Madison Avenue, New York.

elevated, an incision, including only the thickness of the skin and superficial fascia, was begun in front of the left ear, carried downwards along the posterior border of the ramus to the angle, thence close under the body of the jaw, and continued around until it reached the right ear, at a spot corresponding to its starting-point, so that, in a front view, nearly the whole line of incision was out of sight. The left facial artery and vein were soon exposed, tied above and below, and divided between the ligatures. The dissection was then carried to the bone, and the periosteum separated with a blunt steel knife, beginning at about an inch to the right of the median line, under the chin, and extending up to the coronoid and condyloid processes. To avoid its sudden retraction, the tongue was secured by a strong ligature, passed vertically through its substance in the median line near the apex, and confided to the care of an assistant. The periosteum of the buccal surface of the jaw was detached from below, as it could not be reached through the mouth on account of the rigidity of the parts. The whole left side having been so far enucleated, a chain saw was passed into the gap between the right central incisor and left canine, and the bone sawn through a little to the left of the symphysis. Then, seizing this partially liberated segment with the left hand, and depressing and rotating it outward, the temporal and external pterygoid muscles were made tense, and successively divided with the scalpel close to their insertions. Further use of the knife was rendered unnecessary by the previous destruction, by disease, of the capsular and adjoining ligaments, and the bone being free was laid aside. The right segment was detached from its position by a process similar to that described above, but the capsular and other ligaments, which were intact, were divided with the scalpel from before backwards. The vessels, on either side, requiring ligatures were the facial and their submental and masseteric branches, the pterygoidean, and the inferior dental.

The lips of this extensive wound were brought together by six fine silken sutures, on each side, and a few strips of adhesive plaster; and the ends of the ligature which held the tongue were brought out, one at each corner of the mouth, and secured to the cheeks by adhesive plaster.

Before the patient recovered from the effect of the anæsthetic, a dose of ten minims of Magendie's solution of morphia was administered hypodermically, and this was repeated twice daily for five days, during which time she lay in a somnolent state and had to be roused to be fed. Her diet consisted of beef-tea and milk-punch. She said afterwards that during those five days she had experienced no pain whatever.

The greater part of the wound healed primarily, and the sutures and the ligature confining the tongue were removed on the third day. Four weeks after the operation, a slight facial erysipelatous blush appeared, but soon subsided under the application of evaporating lotions and the internal administration of chloride of iron. In May, 1864, the patient was discharged from the hospital, the remainder of the wound (at the seat of the cloacæ) having nearly healed.

The patient called upon me on June 5, 1865, feeling quite well and strong. Her appetite was excellent, her food consisting chiefly of hashed meats and potatoes, eggs, bread and butter, and cream. She had gained very much in weight, and her condition was all that could be desired under the circumstances. I last saw her in September, 1871, seven and a half years after the operation, when she was in excellent health, and when I took the opportunity, as I had done before, of making a careful examination of the parts with a view of ascertaining the extent of bone production, which I found to consist of a thin rim or plate including the mental portion, and the body and part of the ramus on either side, all of which existed in June, 1865.

The pathological description of the parts removed will be given elsewhere. I have lately learned that the patient was in 1874 seized with variola, from which she died, and that no autopsy was made.

It is unusual, in cases of phosphorus necrosis, to find an involucrum, but in the case just reported there was a large one, and, on the other hand, very little of the "pumice-stone deposit" so frequently seen. This is probably to be accounted for by the existence of violent phlegmonous periostitis in the preceding year.

Another point to which I wish to call attention is the method of making the incision. Various lines of external incision have been suggested from time to time, but I wish particularly to elicit the opinion of the Section in regard to the intrabuccal operation, which, as applied to the entire bone, is said to have originated with Signoroni, in 1843.

It is generally considered safer to divide the operation of extirpating the lower jaw into two sittings, removing one-half at a time; but Heyfelder advises that the whole operation should be done at once. Nearly all the cases included in my table were operated on at different sittings, the intervals in some instances having been as long as six months. I have, however, tabulated them as single operations, as the removal of the second half of the bone is but the completion of a previously unfinished proceeding.

Discussion on Dr. Gouley's Paper.

After the reading of the preceding paper, Dr. J. C. Hutchison, of Brooklyn, said:—I think that the intrabuccal form of incision is an unsafe one for the removal of malignant tumors, since there would then be a greater probability of leaving behind some portion of the diseased tissue, but for the removal of sequestra, or even of the bone itself, I consider it perfectly feasible. It is even more applicable to the upper than to the lower jaw, as external incisions in the region of the superior, are more difficult to conceal than those in the region of the inferior, maxillary bone. I have myself, by this plan, broken up and removed the whole upper jaw, together with the malar bone and even the orbital plate.

Dr. Frederick Hyde, of Cortland Village, N. Y., said:—The circumstances of the individual case, the location of sinuses, etc., should determine the form of incision. For the removal of sequestra I usually employ the intrabuccal operation, but for other cases I make such incisions as seem best suited to the accomplishment of the object.

The President, Mr. Lister, of Edinburgh, said:—I was yesterday shown a specimen, in the Museum of the Pennsylvania Hospital, from a case in which more than half of the jaw had been removed by Dr. Hunt, from within the mouth; and I was informed that the patient had recovered with very slight deformity. I do not think that the intrabuccal incision is permissible in malignant disease, but for other tumors it may be practised when the circumstances of the case admit of its use. An external incision, however, gives the operator much more freedom for both sight and manipulation, and, especially in the male, I should prefer its employment in the majority of cases in which the entire jaw was to be removed; even in females the scar can be partially concealed behind the ramus and beneath the base of the jaw. The method of Maisonneuve, which consists in making the incision further forward and thus avoiding the facial nerves, is also a good one, and I have recently removed half of the jaw by a median incision, the resulting scar being but slight.

THE CAUSES AND GEOGRAPHICAL DISTRIBUTION OF CALCULOUS DISEASES.

BY

CLAUDIUS H. MASTIN, M.D.,

OF MOBILE, ALABAMA.

In investigating the etiology of calculous affections, it will be necessary briefly to examine the composition of the secretion in which they take their origin, to see what is the normal condition of the fluid, so that we may observe any changes which take place in its departure from a standard of health. In this research, we must consider the relation between healthy or normal urine, and urine which has been changed by blood alterations; we must observe the causes which produce those changes, and then decide upon the probable causes which induce the formation of urinary calculi.

Healthy urine is composed of certain constituents, water being the menstruum which holds in solution the organic products of digestion and assimilation. First among those ingredients characteristic of healthy urine, which are furnished from destructive assimilation of the tissues and separated from the blood by the liver and the kidneys, are, urea, uric acid, creatine, coloring matter, and odorous principles. Secondly, and derived chiefly from the food during the process of assimilation, are, hippuric and lactic acids, together with certain accidental constituents, and also some inorganic products—saline combinations which have been separated from the blood, such as the sulphates, the phosphates, and the chlorides, of which the bases are respectively soda, potassa, lime, and magnesia; soluble salts which have been introduced into the economy along with the food, and have undergone decomposition in the system, or such as have entered into new combinations during the process of destructive assimilation, as is especially the case with the sulphates and the phosphates. In addition to these, we find certain ingredients derived from the lining membrane of the urinary passages, as the débris of epithelium, from the kidneys; mucus, from the bladder; and phosphate of lime, the result of the decomposition of mucus and pus in cases of cystic inflammation.

We know that, during health, the composition of the blood is continually changing by the introduction of new matter through the process of digestion, the *primary* assimilation of the food; and that it is constantly being altered by the presence of waste or effete material, the result of the breaking down of the tissues in the course of nutrition, or *secondary* assimilation. Then we find constant changes going on, the result of excretion by the liver, the skin, and the kidneys; changes which control and govern the healthy condition of the urine, and any departure from which produces certain pathological alterations, which are either *general* or *special*. We also know that, in disease, the blood is constantly undergoing change in its component parts, receiving new material of a morbid character through the process of either primary or

secondary mal-assimilation, or through the co-operation of both; the first representing the process of deficient digestion, the latter of faulty nutrition. The blood is necessarily changed when these morbid matters are not properly eliminated, as is the case when we have mal-excretion by the kidney, liver, skin, or other secreting and excreting organs.

Now, as *general* pathological changes depend upon some general systemic disorder, as, for example, fever, rapid waste of tissue, anæmia, etc.; so also *special* changes depend upon some special unnatural ingredient present in the circulation and showing itself in the urine, as, for instance, albumen or sugar; or some natural constituent may be present in unnatural proportion, and thus form a leading feature in disease; or again this natural constituent may become so altered in its physical condition as to produce a particular morbid state, as when uric acid in combination with soda gives rise to gout, or when uric acid, oxalate of lime, earthy salts, and such materials, produce calculous concretions.

Whenever we have mal-assimilation in the process of nutrition, one of its consequences is what Liebig has termed "destructive metamorphosis" of the tissues: and, as the various tissues are composed of certain chemical constituents, we have as the result of their disintegration particular chemical agents which bear upon and constitute a diathesis. For example, when those textures which are rich in albuminous material are broken down, they furnish an amount of lithic or uric acid which surcharges the blood, and gives us the expression, "a gouty diathesis." Like changes taking place in the destructive metamorphosis of highly nitrogenous tissues, as the muscular structures, or even where obstinate constipation has locked up in the alimentary canal the excrementitous residue of ill-digested food, urea is formed too rapidly for elimination, and it is also found in excess in the urine. Then, again, when the brain and nervous system become overtaxed from any cause, a consequent prostration follows, and, abounding as they do in phosphoric acid, the result of this destructive metamorphosis, so to speak, is an excess of the phosphates, and we have what is known as the "phosphatic diathesis." Here we find the débris of the nervous system adding an undue proportion of phosphoric acid to the blood, a combination resulting with its alkaline and earthy bases, and, as a consequence, a deposition of the phosphates in the urine. In certain conditions of the bladder, as in cystitis of long duration, or in enlargements of the prostate where a change has taken place in the mucous membrane, these salts become precipitated, and phosphatic calculi result; injuries to the spine, from which paralysis follows, produce similar results.

Following this course of investigation, we see that when there has been a destructive metamorphosis of the gelatinous tissues, there is a conversion into oxalic acid, which, entering the circulation, gives an "oxalic acid diathesis," with a tendency to deposit of oxalic concretions. In like manner, we could trace the formation of sulphuric, hippuric, and lactic acids, and show that a destructive metamorphosis or transformation of the tissues in general will produce the chlorides.

We also observe that, during the process of digestion, changes take place in *primary* mal-assimilation, by which certain constituents enter the blood in the same manner that they do during the process of *secondary* mal-assimilation, or destructive metamorphosis of tissues. These changes are referable to the stomach, duodenum, and chyliferous organs, and thus it is that we find lactic or uric acid the result of imperfect digestion of albuminous food, urea following an excess of nitrogenous material, or

the phosphates resulting from an undue proportion of alkaline ingesta uniting as a base with the free phosphoric acid contained in other articles of food which were eaten at the same time. Then, again, we find that certain articles of food supply certain chemical constituents which enter the circulation during the process of digestion; for example, oxalic acid is derived from special articles of diet, as sorrel, rhubarb, tomatoes, and similar articles, and this acid, acting on the lime contained in hard water which may be drunk at the same time, furnishes the oxalate of lime, one of the varieties of urinary calculi. In the same way an excess of sulphuric, lactic, and hippuric acids, is formed from articles of food in which they respectively abound.

Without pursuing this line of thought or reasoning further, we now turn to the process of mal-excretion, and perceive that certain structural or functional alterations of either the kidney, liver, or skin (the great depurating emunctories of the system) may interfere with their healthy action, and, through a faulty process of elimination, cause an excess of the urinary constituents to remain in the blood, thus constituting a diathesis referable to the particular ingredient which may predominate. Where uric acid is the morbid product, we have a blood change giving the expression of a uric acid or gouty diathesis, which may under certain circumstances develop a gout, and under others precipitate urinous salts in the pelvis of the kidney, and give rise to sand or gravel. For during the process of elimination, uric or lithic acid is separated from the blood in combination with a base, as soda or ammonia; the former necessary for the production of gout, the latter for the formation of gravel; and as both of them are soluble in the urine only when they are not in excess, and when the urine is at the normal temperature of the body, it follows that they must become precipitated whenever they exist in abnormal quantities, and whenever the urine is changed in temperature.

If from any cause we have a structural alteration of the kidney by which the proper excretion of these substances is prevented, they must as a consequence be either retained in the blood, or stagnate, so to speak, in the tubules of the kidney, and thus give us the disease of that organ, as a cause for the effect. In the same manner, the skin, acting as a great depurating organ, eliminating effete material from the blood, becomes by any arrest of its particular function (either from disease or accidental causes) a factor in the production of certain pathological conditions, as for example, rheumatism and nephritis; and certain structural alterations of the liver give rise to functional irregularities, which leave special morbific matter in the circulation, and thus produce a blood alteration which may aggravate an existing diathesis; for, when "oxidation is imperfectly performed in the liver, there is a production of insoluble lithic acid and lithates instead of urea, which is the soluble product resulting from the last stage of the oxidation of nitrogenous matter." We see this even in health, when individuals surfeit themselves by an excess of food which is over rich in nitrogenous principles.

There are some persons who, from habit, are remarkably prone to form lithic acid in the liver, and, when this tendency exists for a series of years, a diathesis is formed which controls the system, and the constant production of the lithates establishes either gout or calculus; for whenever a diathesis produces in one person the lithate of soda, and in another plain uric acid, it can with propriety be said to give rise to two different affections, two different series of phenomena which spring from one and the same root. Hence it is that we infer the identity of the causes of

gout and calculus; the same causes which operate in the production of the one, bear upon the formation of the other. Therefore as gout depends measurably upon lithæmia, so also urinary calculi depend for their origin upon certain functional derangements of the liver acting in concert with special affections of the kidneys, such as catarrhal inflammation of the urinary passages over-stimulated by an acid state of the urine.

Next in frequency to uric acid, the *oxalate of lime* is the most important constituent entering into the formation of urinary calculi, at one time forming the entire concretion, at another only the nucleus around which other urinary salts may collect. This is not one of the normal constituents of the urine, but is found frequently as a deposit, being probably produced through uric acid from the nitrogenized material of the food or tissues—oxalic acid combining with the lime in the economy and forming the oxalate of lime. Time will not permit me to enter into the various theories advanced as to the production of this substance in the system, and hence I will not refer to them.

This product is never present in the form of sand, as is the case with uric acid, but often exists in microscopic calculi composed of dumb-bell crystals aggregated together; we detect it also in the system in almost every form of debility, often in febrile affections, and most usually associated with an excess of urea. When this condition exists, we have what is termed "oxaluria," a condition of the system referable to some interference with healthy respiration; possibly produced by chronic bronchitis, emphysema of the lungs, affections of the liver, or exhaustion of the nerve centres from either mental or physical labor, or, in some individuals, the result of excessive alimentation during a too sedentary life which interferes with healthy digestion and assimilation. It is evident that this particular substance is the result of a retrograde metamorphosis both of food and tissue, and hence it is unnecessary again to refer to its production from special articles of diet. There is, however, one circumstance deserving notice, which is the uniform constancy of the relative proportion of oxalic and uric acid, a condition which exists uniformly and which suggests the inference that the same causes are at work in the production of both; especially is this the case when we notice the remarkable correspondence in the proportion existing between the nuclei of the two varieties, showing that they are very closely allied, and that the tendency to form one or the other in different individuals depends solely upon some particular idiosyncrasy.

Cystic and xanthic oxides are so very rare that we will not consume time in their investigation, but close this portion of our subject with a brief notice of the phosphates, which do exist in normal urine; uncombined, however, they are insoluble, being only held in solution by the presence of free phosphoric acid. Hence it is that calculi composed of the phosphates are not very common as constitutional calculi, and as nuclei they are exceedingly rare.

It is not necessary to consider the circumstances which cause the presence of the earthy phosphates in the urine, but it is essential to investigate the conditions which determine their precipitation; these depend entirely upon an over-alkaline state of the urine, which has been rendered so by the presence of ammonia, the phosphate of ammonia and magnesia being precipitated as crystals from the urine in combination with the phosphate of lime; here the ammoniacal condition does not arise from an increased excretion of ammonia, but is the result of the decomposition of urea, setting free carbonate of ammonia and water.

This state is favored by any persistent obstruction to a thorough evacuation of the bladder, producing an irritated or inflamed condition of the mucous membrane, and causing it to secrete a muco-purulent discharge; this discharge contains an alkaline pus which is acted upon by the phosphoric acid present with the phosphates of ammonia and magnesia (which are held in solution in the urine only by the excess of this acid), and the salts are precipitated in the form of insoluble phosphates. Such conditions are favored by enlargement of the prostate, which prevents complete evacuation of the bladder, the retained urine becoming decomposed, and the free ammonia given off, increasing the cystitis and reacting upon the pus, forming an adhesive gelatinoid mucus which cements and binds together the precipitated phosphates in a mass. In the same way the presence of gravel or foreign bodies in the bladder produces cystic irritation with its resulting ammonio-phosphatic deposits, and thus calculi of this nature are formed.

We have now shown that all calculi are either of local or constitutional origin; that local calculi depend for their cause upon some disease either primary or secondary within the bladder, whilst constitutional concretions are dependent upon some vicious action—some error of assimilation inherent to the system; and constitute by far the larger proportion of all urinary deposits. For convenience of description, we will divide calculi into two classes: the *first* including all those formed of uric acid and the urates of ammonia, soda, lime, and magnesia, with the rarer forms of uric or xanthic oxide, and fibrinous and blood calculi; the *second*, embracing the various phosphatic deposits and the combinations of the oxalates.

In examining different collections of calculi, it has been discovered that three-fifths of all calculi met with in adults of all ages are composed of uric acid and the urates, nearly two-fifths are phosphatic, and only some three or four per cent. are oxalate of lime; three-fifths, then, are the product of urine abounding in an acid, of which they are the expression; the remaining two-fifths are the products of urine, generally alkaline, mostly ammoniacal, of which they are the result. It follows, then, that the urates, the oxalates, and a few of the phosphates, which are formed in the kidney, must be the result of certain constitutional derangements; whilst, on the other hand, the phosphates, which, whether pure or mixed, are produced solely in the bladder, must be the consequence not of constitutional but of local disease within the bladder itself.

Hereditary Influence.—In 1776, just one hundred years ago, Scheele discovered uric acid; and so frequently is it now observed to form the leading constituent of urinary concretions, that, with Dr. Owen Rees, who has examined the subject most closely, we may safely state that, "without its presence, calculi would become much less common than they are." This being true, we first consider calculi in reference to this constituent. In doing so, we perceive that in all those cases in which uric acid is in excess, a particular diathesis exists—a diathesis which may have been acquired, but which in all probability has been intensified by some pre-existing habit of the system referable to hereditary causes; in fact it may be safe to state that it nearly always depends upon a previous vice of constitution which is entirely hereditary, for if we examine the history of one of these cases, we will almost surely find hereditary causes at work in its production, and, as Sir Henry Thompson has remarked, "either gout or calculi will be traced in the family of nearly every patient who presents himself for treatment."[1]

[1] Sir Henry Thompson, Preventive Treatment of Calculous Diseases; London, 1876.

We all recognize the hereditary tendency of gout—a fact too well established to admit of a question; therefore, as gout depends in a very great degree upon the formation of urate of soda in the system; and as five-sixths of all renal concretions and vesical calculi which have recently descended from the kidney are composed of uric acid (substances so very nearly the same), we infer that hereditary influences have controlled the one as well as the other. It is very true that hereditary tendencies vary in force in different families; that some members manifest the peculiar diatheses under which they labor, at one period of life, whilst others of the same family develop the same disease at another, and that particular circumstances, or accidental causes, control the pre-existing tendency, and either hasten or retard the affection; thus, for example, we see some members of a family suffering from gout in youth, others in middle life or old age; and likewise we find some who develop a calculus in infancy, others not until adult life; or gout and calculi may alternate, one generation producing the one, and the next the other; or then again we may meet a person with gouty symptoms and deposits of chalk stones, which after a lapse of years subside, when a uric acid gravel may form in the kidney. Here we certainly have a manifestation of two different effects which arise from one and the same cause. I am aware that hereditary influences, as causes of calculi, have been questioned by many of our best informed investigators of this subject; but in view of such facts as have been produced from the concurrent testimony of Civiale, Le Roy d'Etiolles, Thompson, and others of like reputation, I am led to believe that hereditary influences stand first in the scale of causes which produce calculous affections.

Seeking a cause for this particular diathesis (uric acid), we find it in a great measure due to defective assimilation in the organs forming the primæ viæ; we see the stomach failing to digest food in a proper manner; primary mal-assimilation furnishing improper materials for the healthy constituents of the blood; the liver defective in its action, and failing to excrete its due proportion of the urinary salts; the solid constituents of the urine becoming augmented; and the over-worked kidneys unable to eliminate the excess of uric acid from the super-saturated blood, the remainder being thus precipitated in crystalline form. Uric acid being very insoluble, unless in a large proportion of water, and that too at the normal temperature of the body, it follows that whenever the solution becomes denser, or its temperature lowered, the uric acid must be precipitated and left in some portion of the urinary organs, forming in the kidney renal calculi which afterwards become vesical.

As we have seen a certain diathesis cause an excess of uric acid and the urates, so likewise it can be shown that other trains of circumstances will provoke diatheses which produce the other varieties of calculus.

Climatic Influences.—Climate doubtless exercises more or less influence in the production of these affections, for in very changeable regions calculous diseases are more common than in those localities where a more equable temperature exists. This is especially the case in the temperate zones, whilst in very cold or hot countries the disease is not so frequently met with. Still there are certain districts of the earth's surface, bounded by the same lines of latitude and longitude, and subject to the same climatic influences, that develop the disease in one section, whilst in another section similarly situated it is never encountered. This is especially noticeable in England and the United States.

Calculous affections are much more frequent in Kentucky, Ohio, Virginia, Tennessee, and North Carolina, than in any other portions of the United States, although we have a vast area of territory similarly located, geographically, geologically, and climatically, in which stone is rarely if ever encountered. The same may be said of England, where calculus is very common around Norfolk and Manchester, while in other regions which are within the same latitude, and subject to the same temperature, it is almost unknown. This is also the case in Hindostan and those portions of China in the vicinity of Canton; there, calculous disorders abound to a greater degree than in any other parts of the globe. These countries are noted for their variableness of temperature, which is one of the causes assigned for the frequency of this disease; and it may be possible that a due regard to a change of clothing is not sufficiently observed at such times as these changes occur, and that this neglect may have an important bearing upon the subject; for when the skin is not properly protected, its functions become disturbed, and the kidneys are required to perform an excess of labor.

Poverty.—The poorer classes are more liable to the affection than the rich; and it may be noted that they are worse fed and worse clothed than those in more affluent circumstances. Upon such a class of the population, climatic changes have a more depressing influence, and in this way may prove a cause of the affection.

Food.—The belief that food is one of the causes of calculous affections, is probably not altogether without foundation; for we find certain articles of ingesta, already mentioned, which have a tendency to induce acidity with flatulence, and thus directly produce dyspeptic troubles which may light up a diathesis lying dormant. Dyspepsia being one of the most usual of the causes of calculus, almost any article of food which deranges the function of assimilation, may stand in relation of cause to the effect. Highly nitrogenous food, when combined with acescent ingesta, increases the deposition of uric acid, and lessens the formation of the phosphates in the urine; again, an almost exclusively animal diet contributes to the rapid formation of uric acid, and, in persons who labor under a calculous diathesis, lays the foundation of stone. We believe that the various articles of diet which are considered productive of calculous concretions, are so secondarily, first producing irritation in the alimentary canal, followed by dyspepsia with mal-assimilation of the food, and thus becoming the remote cause of the affection; it is not probable that food properly digested is ever the cause of calculus.

Water.—Excepting in the case of oxalate of lime concretions, it will be safe to assert that water does not exert any direct effect upon the production of calculus. It is very true that, in the case of the oxalic variety, water may furnish a proportion of lime, which being acted upon by the acid, will produce the oxalate of lime deposit, but in regard to the other varieties, we see no sound reason urged, why it should be considered as a direct factor in their production. The assertion that water is a cause of calculus, is not sustained by the facts in the case, analyses of the calculi themselves proving that none of them correspond in chemical composition with the salts which exist in the waters drunk in those districts where the calculi make their appearance.

It is self-evident that the only way in which water could have any influence in the formation of calculi, would be by causing a deposit of those salts which exist naturally in the urine itself; and to this end they would have to be of alkaline reaction, and this would favor only a phosphatic

deposit; but even this view is not sustained by experience, for, on the contrary, alkaline waters, such for example as those of Vichy and Vals, and others of like constituents, enjoy a reputation for counteracting a calculous tendency, and even for dissolving the stone when formed. Then again the water of the Seine abounds with carbonate of lime, and were we to attribute to its use the calculous affections which are so frequent in and around Paris, we would naturally expect to find calculi composed of carbonate of lime; but both observation and analysis prove that carbonate of lime calculus is the least frequent of all varieties.

The same may be said of other regions where stone is prevalent. The sandstone districts of Kentucky and Tennessee, where soft water is used, furnish just as many cases of calculus as do the limestone sections where hard water is commonly drunk; and in Alabama, where stone is but seldom encountered—there having been only some fifty to seventy-five operations performed upon her natives since the settlement of the State in 1817—it is a fact worthy of consideration that the greater number of cases has originated in a belt of country running east and west through the State, just above and including Tuscaloosa; a pure sandstone region, with the softest and best water in the State. On the other hand, the northern and eastern sections abound in blue limestone, and the water is very strongly impregnated: yet we rarely, if ever, hear of a case of either gravel or stone within these limits. Again, in middle and southern Alabama, the base of the soil is what is known as "rotten limestone," and the water strongly alkaline; this is also the case in eastern Mississippi, and still we have been unable to obtain reliable information of even a half dozen cases of stone having ever occurred in these regions.

The testimony of Dr. James Guild, of Tuscaloosa, who has been the leading physician and surgeon of that vicinity for the last forty years, and who has probably operated for stone a greater number of times than any other surgeon in Alabama or Mississippi, is, that his cases have all come from the sandstone districts where soft water is commonly used.

Many other interesting examples could be brought forward to prove that water does not directly favor the production of calculous affections, but the time allotted for the reading of this paper will not permit an extended investigation of the subject. It may be well to suggest, however, that hard water as a constant drink may secondarily become one of the causes of stone, by deranging the digestive organs.

Exercise.—Deficient exercise is an important factor in the production of these concretions; they being more frequently found among those who are engaged in sedentary pursuits than in that class which leads a more active life. Inhabitants of large and densely crowded cities, as Paris, for example, who are confined within doors and live chiefly upon a stimulating diet of a highly nitrogenized nature, with deficient respiration and neglect of necessary muscular exertion, become fit subjects for the invasion of dyspeptic troubles, which, when supervening upon an hereditary diathesis, favor the formation of uric acid, with its sequelæ gout and calculus.

Respiration.—Respiration, which is in a great degree controlled by the amount and character of exercise taken, exerts indirectly a powerful influence over the production of the urinary salts. We have shown that a large proportion of all urinary concretions are composed of uric acid, and that this acid is usually precipitated in the form of one or another of the urates. We know that, in health, there are only about eight grains of this acid excreted per diem, whilst of the well-known substance

urea (which, on account of its greater solubility, is never precipitated) there is nearly half an ounce separated from the blood daily by the kidneys. Now, chemical analysis shows that the only difference between these two substances is the varying amount of carbon and oxygen present in their composition; uric acid being represented by the formula $C_{10}N_4H_4O_6$, while the composition of urea is $C_2N_2H_4O_2$. If then the principal difference is made up by carbon and oxygen, the elements of carbonic acid, we naturally refer an excess of uric acid in the circulation to that process by which carbonic acid is produced, and we know this to be respiration. Hence we infer that deficient exercise, by interfering with free respiration, healthy digestion, and assimilation, favors the production of calculous concretions.

Age.—Next in order, age seems to exert an influence in the production of calculi, the urine of infants being more abundantly supplied with uric acid than that of adults; which condition is doubtless the result of the rapid changes to which they are exposed, only a few hours after birth, cold, light, and deficient or improper nourishment, tending to disarrange the proper performance of the functions of their various organs. Taking into consideration their defective digestion, errors in their diet, the irritation of dentition, with the consequent excitement of the brain and nerve-centres, we find them in the very pathological condition most favorable to the formation of a diathesis which, when acted upon by hereditary influences, will produce these deposits.

It is not probable, however, that calculous affections are a great deal more frequent among infants and young children than among adults, although statistics would lead us to infer that such was the case, since these go to show that operations for stone have been performed oftener upon children than upon adults, and more frequently upon the aged than those in middle life; but when we investigate the subject, we find, as Mr. Coulson has remarked, "that an error has crept in from not using the proper precaution to distinguish between absolute and relative numbers. To determine liability, the absolute numbers should be corrected by the numbers of persons living at the several periods of life enumerated. Thus, if all persons under twenty were affected with stone, and all over seventy were affected with the like complaint, it is evident that the liability would be the same, though the absolute number of persons attacked would be very different." Then, to enable us to determine the liability of children of a certain age to stone, we must correct the absolute numbers by the numbers of persons of all ages living at the several periods of life enumerated. Corrected in this manner, statistics would most probably show that young persons are much less liable to calculous affections than is generally believed. In fact, we have observed that in India, where stone is exceedingly prevalent (more so, perhaps, than in any other section of the world), old men are more liable to the disease than any other class of the population.

Sex.—Sex has been considered as exercising some influence over these affections, simply because stone in the bladder is comparatively infrequent among females. This is no doubt chiefly due to the fact that they have short and large urethræ, without prostatic portions, thus affording a ready exit to the nuclei of stone which pass to the bladder after having been formed in the kidney. We are not aware of any reason why the female is not as liable to the formation of calculous concretions within the kidney, as the male; for women are subject to the same general laws and affections which produce the disease in the other sex. Indeed they are liable to,

and frequently suffer from, attacks of calculous nephralgia, and are oftentimes the victims of gout, when exposed to the same exciting causes and when governed by the same hereditary influences which produce these diseases in men.

Race.—On the other hand, race evidently does exert a direct bearing upon the formation of these concretions. In America, where we have ample opportunities of examining the subject, it has been shown that calculous affections are exceedingly rare among the negro population, and that gout is seldom, if ever, seen in the black. During the past year, I have been engaged in collecting statistical information of American lithotomies, and in examining the various reports in reference to this point, I find that out of some 3039 reliable cases which I have to this date tabulated, there are only 102 operations reported as having been performed upon the negro, and only 31 upon the mixed blood or mulatto. Similar observations have been made among the native African tribes, and stone has not been found as a frequent affection. Dr. Thomas Winterbottom states, in his Medical History of the Native Africans around Sierra Leone, that "notwithstanding the excesses committed by the pagan nations of Africa in the use of spirituous liquors, etc., I have never heard of an instance of gout among them, nor is it probable that they are acquainted with the disease;" again, he says, "except gonorrhœa, I have never met with any affection of the urinary passages, such as gravel, calculus, etc." This is further corroborated by the testimony of Dr. Livingstone, who states that "stone in the bladder and gravel are unknown; I have never met with a case, though the waters are often so impregnated with sulphate of lime that the kettles quickly become encrusted with the salt, and some of my patients who were troubled with indigestion, believed that their stomachs had got into the same condition."[1]

This apparent immunity from the affection cannot be due to color, for we find some of the dark-skinned races, as for instance the Asiatics, exceedingly prone to the disease; and in the peninsula of Hindostan, especially in the central and upper provinces, stone is met with probably more frequently than in any other locality of equal extent on the earth. In a paper upon this subject, by Dr. Curran, of the East India Service, it is mentioned that "from Peshawur to Calcutta the diathesis is general and almost universal;" and we note that at the Medical Missionary Society's Hospital, at Canton, Dr. J. G. Kerr operated for stone more than 300 times in the short space of three years. Other instances of the remarkable frequency of this operation at the hands of the native surgeons of India could be cited if it were necessary to do so.

Like the negro or black man, the aboriginal tribes of North America seem to be peculiarly exempt from stone affections; whilst, on the other hand, the white races are its constant victims—a fact which evidently can be used as an argument to prove the influence of race in the production of a diathesis favoring the formation of stone. If not, how else shall we explain the fact that the negro and North American Indian are exempt in a great degree from an affection to which the white man, and his darker complexioned Aryan brother of Asia, are so liable?

Habits.—It is possible that habits and modes of life of the white races may influence in a great measure the production of the disease, exposed as they are to all the cares and excitements of civilization; inhabiting sections of the globe subject to sudden vicissitudes of climate, with all

[1] Livingstone, Missionary Travels and Researches in Central Africa.

the errors of a life which is not led in accordance with the great laws of nature, it is reasonable that we should find stone more frequent with them than in those races which live in a comparatively natural state.

On the contrary, the negro and American Indian are not only accustomed to a life in the open air, and to a diet suited to their digestion, but having the finest teeth, they masticate their food properly, and thus still further favor healthy digestion. Their skins are more active, and, as great depurating organs, eliminate much effete material which in other races must pass off by the kidney. It is also probable that some inherent principle exists in the negro which in a great measure exempts him from this disease, just in the same way that he is to a degree exempt from certain fevers and other affections. What that principle is, I am at a loss to suggest. The inhabitants of India live principally upon rice and other cereals—materials rich in nitrogenous matter, and, being careless in guarding themselves against sudden changes of temperature by suitable raiment, they invite as it were the formation of a uric acid diathesis; and any exciting causes which supervene to disturb the normal relations of the urinary constituents must naturally tend to produce calculus.

Occupation.—Certain occupations seem to exert an influence in preventing or producing these affections, seamen and soldiers being peculiarly exempt; so much so, that it is a noticeable truth that the disease is rarely met with in persons who follow either of these modes of life. Civiale in his large experience saw only three cases among sailors; and Mr. A. Copland Hutchison states that, in the British Navy, with a number of patients estimated at 86,000, there were only eight cases of stone encountered in sixteen years, and that three of these were afflicted with this disease before entering the service. The records of the Greenwich Naval Hospital, during a period of twenty-seven years, show that not a single operation for stone had been performed. This is equally true of the American Navy, as there is not a single case reported at our Naval Bureau; and the testimony of Dr. W. S. W. Ruschenberger, Medical Director, U. S. N.,[1] whose experience in this service extends over fifty years, is that he has known of only one operation, and that his personal observation has been confined to but one calculous sailor, who had the disease at the time he enlisted.

A similar exemption seems accorded to soldiers, if we receive the statements of Sir James M'Grigor, which show that out of 340,000 patients, among soldiers serving in the Peninsular Campaign, no case of calculus was met with from 1811 to 1814. Like results are obtained from the French and Russian Army records; and the experience of our late civil war is that there have not been more than two cases of calculus recorded as the result of a systemic condition; although probably the richest collection in existence of stones having bone nuclei, has been collected for the Army Medical Museum, at Washington, through the indefatigable energy of that accomplished gentleman, Dr. Geo. A. Otis, of the Surgeon-General's Office.

Without definite facts to guide us in forming an opinion, we believe that the most probable cause of the infrequency of stone among seamen and soldiers, is that they are generally men in the prime of life, there being comparatively few of either children or old men among them—classes which are considered the most liable to stone; again, the rigid examina-

[1] MS. letters to writer.

tion of recruits for both services, naturally excludes all those suffering from that state of constitution which would favor a formation of such deposits. We cannot, therefore, consider that occupation, *per se*, exerts any protective influence against calculous concretions.

Moral and Physical Emotions.—Very different is it with moral and physical emotions; they evidently exert a powerful causative effect in the production of these affections, and, if time would permit, some very interesting examples could be adduced to prove the effect of the passions—fear, anger, joy, and grief—over the normal secretion of the urine.

Dr. Debout D'Estrées, in his treatise on the "Causes of Gravel and Stone,"[1] narrates quite a number of clinical cases, showing the effect of mental excitement and depression; and M. Bouchardat, in his Memoir upon Gout, gives instance after instance in which violent emotions have produced polyuria; while Civiale himself often remarked how frequently severe exercise and great trouble of mind were followed by the formation of much red sand in the urine.

Foreign Bodies.—We now come to a fertile cause of calculus, which is the presence of foreign bodies introduced into the bladder, either by accident or from design; they irritate and inflame the mucous membrane, thus causing the secretion of an alkaline mucous or purulent fluid by which the urine is rendered alkaline, and hence a precipitation of the phosphates around the foreign body which acts as a nucleus.

Injuries to Spine and Urethral Stricture.—Injuries of the spinal cord produce phosphatic deposits, and thus become one of the causes of vesical calculi; and it has been asserted that stricture of the urethra favors the production of these concretions. In relation to the latter cause, I am inclined to believe that its effect has been over-estimated; for, after having carefully investigated this point, I am struck with the fact that authentic cases of calculus, resulting from urethral stricture, are exceedingly rare. My friend, Prof. Fessenden N. Otis, of New York, says, in a MS. letter on this subject, "in over five hundred cases of stricture, to which I now refer, I have met with but (3) three cases in which stone was coincident with stricture." In my own experience with stricture of the urethra, I find, among the notes of over three hundred cases, that there are but (2) two in which calculus and stricture have been associated; one of them occurred in an old man sixty years of age, suffering from enlargement of the prostate; the other in a youth in whose urethra a small uric acid calculus was lodged in a pouch posterior to the stricture.

It is not improbable, however, that, in very close strictures of long duration, an arrest to the passage of urine may produce vesical irritation and inflammation, causing the secretion of a muco-purulent discharge from the bladder, which will favor such deposits.

Colloids.—Besides the presence of urinary salts, there is something more required for the formation of calculi, for in their natural state the salts are not capable of entering into the agglomerated condition essential to such formations; nor should we consider calculi as mere precipitates of ordinary crystalline and amorphous deposits held together by plain mucus. Some other agency is necessary, and this will most probably be found in the presence of the colloids—certain glutinous products, the result of subacute inflammation of the urinary passages, the kidneys, the ureters, and the bladder itself; they evidently exert an influence over precipitated crystals, changing their forms into amorphous, or, as

[1] Les Causes de la Gravelle et de la Pierre, par le Dr. Debout d'Estrées; Paris, 1876.

Dr. Vandyke Carter[1] designates them, "submorphous structures," which, in the presence of an animal basis, become embedded in the colloid matrix, and thus form calculous masses.

The experiments of Mr. Ord[2] prove that crystalline forms, when associated with a colloid, are altered by two processes—first, by modification of surfaces and angles; and secondly, by a corresponding rearrangement of the molecules themselves. He proved that the strength of a urate solution, with a concentration and excess of the acid supplied, controlled the form of the resulting crystals, and that uric acid, in many of its aspects, verged upon the nature of a colloid. He found that albumen exercised a more powerful influence than any other substance in producing a change of crystalline form, and a disposition to assume an agglomerated condition. Still, we find it difficult to say what is the chemical nature of the animal basis which, in the living being, causes uric acid to change its pure crystalline form to some other, more prone to agglomeration. But, judging from the experiments of Mr. Ord, we conclude that it is albuminous, and, as "mucin" is derived from these formations, probably mucin is the cement.

The general conclusions which we deduce from these experiments are, first, that albumen and the other colloids, when placed in the presence of uric acid, cause its crystals to be deposited in the shape of small, thick, sub-cuboidal bodies, without curved faces, and sometimes as dumb-bells or spheroids; secondly, that grape sugar and other crystalloids cause the acid to be thrown down in long tabulated or foliaceous crystals, with flat sides and sharp angles and edges—forms essential to the process of agglomeration into masses.

Oxalate of lime crystals are in like manner altered in form by the presence of a colloid; but it seems to be requisite that the colloid should be denser than for the same change in uric acid. This fact led Mr. Ord to draw the inference that, as small calculi which pass from the kidney in nephralgic colic are generally of the oxalic acid variety, they are doubtless formed in the recesses of the kidney, where the colloid medium is denser than in other portions of the urinary tract.

The triple phosphates are less frequently influenced by the presence of the colloids than the other varieties, and consequently they are less disposed to form spherical or agglomerated masses.

In the urine we find four groups of substances which are capable of moulding urinary salts into conglomerate masses, and thus of favoring the formation of calculi, viz., mucus, urea, coloring matter, and salts. Standing first among them is mucus, a colloid prone to decomposition, and active as a ferment in promoting putrefaction of organic substances when associated with them in solution; now "an excess of this mucus, altered in character in the urinary passages, or an effusion of albumen, fibrin, or blood, as often results from congestion of the kidney, or from irritation of the urinary tract, will furnish a colloid medium with which uric acid, the urates, or oxalates (themselves perhaps in excess), will combine in the manner before described and thus form a calculous mass."

The microscopic examinations of urinary calculi, by Dr. Vandyke Carter, sustain the views advanced by Mr. Ord, that the spheroidal forms of crystalline masses are not entirely due to the mechanical influences at

[1] Microscopic Structure and Mode of Formation of Urinary Calculi, by H. Vandyke Carter, M.D.; London, 1873.

[2] W. M. Ord, M.B., London, M.R.C.P., St. Thomas Hospital Reports, vol. i., 1870; also Medico-Chirurgical Transactions, vol. lviii., 1875.

work in their formation, and show that there has been a molecule disturbing power acting in the presence of the colloid medium; and also that the form and cohesion of the crystalloids in the formation of calculi may be accounted for by Mr. Rainey's theory of molecular coalescence in the production of shells.

From the microscopic examinations of urinary calculi by Dr. Carter, and the experiments upon urinary salts by Mr. Ord, we are led to the following conclusions: All crystals of urinary salts are modified in shape when they are deposited in a colloid medium; the animal basis of uric acid tends to produce this change; and like causes bring forth the same alterations in the crystals of the other salts. The necessary conditions favorable for the operation of molecular coalescence may at any time be brought into action; and wherever there is an excess of mucus which has been altered in character in the urinary passages, or an effusion of albumen, fibrin, or blood, from congestion of the kidneys, or from irritation along the urinary tract, we have furnished a colloid with which uric acid or the other salts will combine in the manner described. Such a state of system is found during certain fevers, inflammations, etc., where the urine becomes loaded with sediment, and the first nucleus of a gravel begins; this being accomplished, the little nucleus becomes surrounded by a thin layer of protective mucus, in which continued layers in molecular coalescence are deposited, and a calculus is formed.

We do not desire to be understood to say that calculi are accidental formations, dependent wholly upon bare physical causes, but rather that they depend for their production upon an association of hereditary influences with certain physical causes; and that the defects of structural development which we find in certain hereditary conditions probably produce certain elements which are formed into calculi through the agency of the colloids, these being themselves the result of such an hereditary state or condition. It seems necessary for the formation of calculi that these conditions should remain constant and unvarying for a period of weeks, months, or years, thus furnishing time for the slow growth of these concretions.

Time will not permit me to refer to the changes which take place in a calculus after the nucleus is formed in the kidney, and during its passage through the urethra and its lodgment in the bladder; I will, therefore, close with a brief notice of the geographical distribution of calculous affections in North America.

Geographical Distribution of Calculi.—Calculus is not universally found over the Western Continent, there being certain localities where it is met with much more frequently than in others; and then again there are sections where it is almost entirely unknown. The central portions of the United States have furnished more cases than any other parts, whilst the extreme Southern and Northern States rarely produce a case. Along the Gulf coast, the Canada line, and the Pacific shores, stone is very uncommon; as it is also in the Canadas, the British possessions, and Mexico.

In the United States, we find it more frequently in an area of country comprised within the boundaries of Tennessee, Kentucky, Ohio, Indiana, Missouri, Western Pennsylvania, Virginia, North Carolina, and Georgia, than elsewhere; there is also a tract of country adjacent to and including Salt Lake City, Utah, where the disease is said to be remarkably common. On the other hand, stone is comparatively infrequent in Alabama, New York, Maryland, and Illinois; whilst in New Jersey, Delaware, and the New England States, it is so rare that there are very few surgeons who have operated for stone in those States. The Warrens, of

Boston, have performed the greater number of all the operations for this affection which have been done in New England; and that number is very small when we take into consideration the density of the population, and the lapse of time since the settlement of the country. The States bordering on the Gulf of Mexico—Florida, South Alabama, Mississippi, Louisiana, and Texas—are almost entirely exempt from calculous troubles: not more than two or three cases have occurred in Florida; scarcely more in either Southern Alabama, Mississippi, or Louisiana; although in Southwestern Texas, along the Mexican line, quite a number of stone cases have occurred, and have been taken to San Antonio for treatment; but in all other sections of the State the affection appears to be remarkably infrequent. It is a strange circumstance that in the State of Minnesota calculous affections, in the form of nephralgic colic, are exceedingly frequent, whilst stone in the bladder is so very rare; yet this is true, and after a very extended correspondence with the leading physicians and surgeons of that State, I have been able to hear of only three operations for stone upon persons who have resided there. The same may be said of Arkansas, with the difference that gout and calculus are so very seldom seen that they have not been classed among the diseases of the State.

Taking into consideration the recent settlement of Iowa, and its scattered population, it is a little remarkable that stone has been met with so frequently as is shown to be the case by the number of operations reported. To this date I have been unable to gather any reliable information as to the frequency of calculous affections in the far West; but, from the data before me, I am led to infer that they are uncommon. Some few cases of stone have been operated upon at San Francisco, but it has, so far, not been ascertained whether they were of foreign or domestic origin.

In closing, it may be interesting to notice that almost the entire tract of country in which stone has been found to abound, belongs to the carboniferous and sub-carboniferous formations, in which gypsum, limestone, marble, and cretaceous deposits abound; regions the most productive of any others of the temperate zone, furnishing all the varieties of nitrogenous and non-nitrogenous materials of food, both animal and vegetable, the very kind of aliment most calculated to derange the digestive organs.

In summing together the *probable* causes of calculous affections, we place—

I. Hereditary influences which control a diathesis.

II. Digestive troubles produced by an excess or deficiency of proper diet.

III. Sedentary life, with indulgence in stimulating food, by which healthy nutrition and assimilation are altered to mal-assimilation and mal-excretion.

IV. Climatic changes, deficiency of clothing for the proper protection of the body, and an arrest of the healthy function of the dermoid tissue.

V. Want of harmony between the great secreting and excreting organs—the liver, skin, and kidneys—with catarrhal affections of the uropoetic viscera, which favor the formation of a colloid medium.

VI. Injuries of the spinal cord, by which a proper nervous influence over the mucous membrane of the urinary organs is lost.

VII. Foreign bodies present in the bladder, producing cystitis with its consequent muco-purulent discharge, and becoming nuclei upon which the phosphates are precipitated.

SUBCUTANEOUS DIVISION OF THE NECK OF THE THIGH-BONE FOR ANCHYLOSIS AT THE HIP-JOINT.

BY

WILLIAM ADAMS, F.R.C.S.,

PRESIDENT OF THE MEDICAL SOCIETY OF LONDON, ETC.

9

Mr. President and Gentlemen:

The observations which I propose to offer to-day for the consideration of the Surgical Section of the International Medical Congress, refer to the operation of subcutaneous division of the neck of the thigh-bone for anchylosis of the hip-joint, with malposition of the limb; an operation which was first performed by myself in London at the Great Northern Hospital on the first of December, 1869. I propose to refer to the experience which we have gained during the past six years, since its first performance, as far as I have been able to collect records of the cases operated upon; and to offer some observations on the mode of performing the operation, the selection of appropriate cases, and the results to be obtained as to the permanent condition of the limb, *i. e.*, whether anchylosis in the straight position is to be the result, or whether we are to endeavor not only to rectify the deformity, but to obtain a false joint at the seat of operation with free voluntary motion of the limb.

Anchylosis of the hip-joint may result from any inflammatory affection of the joint, and formerly, or I would rather say in our own time, under the teaching of Sir Benjamin Brodie, and the generation of surgeons now just passing away, this was the result which all surgeons desired to see as the termination of hip-joint disease, as well as other joint affections. Their treatment was directed to the production of this result by long-continued and absolute rest, with the application of straight and immovable splints. In connection with the subject of anchylosis, it is important that it should be borne in mind that its prevention in a large number of cases, and prevention is always better than cure, is due to the advance of American Surgery; and that Professor Sayre, by disproving one of the old surgical maxims of the English school, that absolute and long-continued rest, and recumbency with a long straight splint or some other form of splint to maintain absolute immobility of the joint, are essential to the cure of the disease—and by substituting his apparatus acting on the principle of maintaining motion during the treatment of the affection—has added a great practical improvement to the modern treatment of hip-joint disease.

As the result of the more severe forms of hip-joint disease, however, anchylosis must necessarily take place, unless resection has been performed, and must be regarded as the best possible compromise, and the best termination of a very formidable disease which threatened even the life of the patient, provided always that the anchylosis has taken place with the limb in a natural and useful position. In the hip-joint, the best position for the patient in which anchylosis can take place, is with the thigh slightly flexed, without any adduction or abduction of the limb;

a little shortening is easily compensated for, and the patient can sit down without much inconvenience in a chair. Anchylosis with the thigh in a perfectly straight position, *i. e.*, so straight that, when the patient is lying on his back on the ground, there is no arching whatever of the spine in the lumbar regions, is attended with very serious inconveniences; the patient cannot sit on a chair except when resting on one buttock on the edge of the chair, the anchylosed limb being stretched out with the heel resting on the floor, and as a result of this habit, in cases of long standing, the knee-joint bends preternaturally backwards; this is increased by a habit sometimes acquired of crossing the sound leg over the anchylosed limb. This condition of straight, it might almost be called over-straight, anchylosis is rarely met with, but I have been consulted by two patients, one a married lady, and the other a gentleman about forty years of age, who suffered so much from this condition of straight anchylosis that they were both anxious to submit to the operation of dividing the neck of the thigh-bone, if motion could be obtained, but as I was unable to promise this, and they had become habituated to the inconveniences, nothing was done. I may mention that it was not only the inability to sit on a chair, which annoyed these patients, but they told me that the bowels could only be relieved in the standing position, so that they were anxious to submit to any operation promising relief if motion could be obtained.

Anchylosis with the limb in a deformed position is, however, the condition for which surgical aid is generally sought. In the great majority of cases of anchylosis of the hip-joint, contraction of the joint with the limb in a deformed position is found to exist; in some cases, simple flexion of the thigh having occurred with very little adduction or abduction; in other cases, severe adduction with a comparatively small amount of flexion, and again, in others, the distortion will be found to depend upon flexion with abduction, or adduction, of the thigh, in about equal proportions. The inconveniences will vary according to the extent and the direction of the contraction, being greatest in those cases in which flexion and adduction are combined, so that the knee of the anchylosed limb is drawn across the opposite thigh; more especially when this occurs in females.

There can be no doubt that an urgent necessity for surgical interference exists in many of these cases, and it was in the city in which we are now assembled that the first operation, having for its object not only that of rectifying the deformity, but of obtaining motion by the establishment of a false joint, was performed by Dr. J. Rhea Barton in the year 1826.[1] A large external incision was made, and the bone sawn through between the two trochanters. The deformity was rectified, and the case proceeded favorably. It is said that useful motion was obtained, but that seven years afterwards anchylosis took place, and the man died of phthisis nine years after the operation. This proceeding, somewhat modified, was afterwards repeated by J. K. Rodgers and others, but the next operation of importance for this class of cases was one also performed by a distinguished American Surgeon, Dr. L. A. Sayre, of New York, who removed a transverse section of the femur, of elliptical form, just above the trochanter minor, by means of a chain saw, the

[1] "On the Treatment of Anchylosis by the Formation of Artificial Joints," in the North American Medical and Surgical Journal, April, 1827, with further remarks in the American Journal of the Medical Seieuces, vol. xxi.

external incision being necessarily of large size. This operation Dr. Sayre successfully performed on June 11, 1862, and as late as April, 1868, the patient is reported as able to walk with free motion of the limb. Dr. Sayre repeated this operation on November 6, 1862, and the case proceeded favorably at first, but abscess with some necrosis of bone occurred, and the patient died of tubercular deposits in the lungs with pneumonia on May, 17, 1863. It was found, however, that a very perfect artificial joint had been formed, and that so far the object of the operation had been accomplished.

I shall next refer to the case in which I divided the neck of the femur subcutaneously at the Great Northern Hospital in London, on December 1, 1869.[1] A case of bony anchylosis of the hip-joint with the leg in an extremely deformed position came under my care at that time, the leg being flexed at a right angle, and abducted, in a man aged twenty-four. It occurred to me that the neck of the thigh-bone was the spot to which attention should be directed, and that if I could divide the neck of the bone by means of a very small saw passed through a wound not much larger than that made by an ordinary tenotomy-knife, and thus preserve the true subcutaneous puncture, I should be able immediately to cure the deformity, and might, perhaps, succeed in obtaining motion. The instruments used were a long tenotomy-knife, and a very small saw three-eighths of an inch in width, and with a cutting edge an inch and a half in length, made by Mr. Blaise, of 67 St. James Street, London. I entered the tenotomy-knife a little above the top of the great trochanter, and, carrying it straight down to the neck of the femur, divided the muscles and opened the capsular ligament freely. Withdrawing the knife, I carried the small saw along the track made—preserving this by pressure of the fingers—straight down to the bone, and then across the anterior surface of the neck, the flat side, and not the edge, of the saw being applied to the bone as it was gently carried along its anterior surface; the edge of the saw was now turned upon the bone, and by a very wiggling sawing movement the section of the bone was accomplished in five minutes. No hemorrhage followed, and I immediately applied a compress of dry lint, retained in position by strips of adhesive plaster and a bandage.

As soon as the bone was cut through, the leg moved freely in all directions; but, before it could be brought into a straight position, it was necessary to divide the tendons of the long head of the rectus, and of the adductor longus muscles, and to cut through the tensor vaginæ femoris muscle. The limb was fixed in a straight position, and bandaged to a long interrupted Liston's splint. No inflammation whatever followed the operation; no swelling, or redness of the skin, or any deep suppuration, but the wound healed slowly, two or three drops of pus in the day oozing from the track of the wound or the granulations at its orifice for three weeks. This did not prevent my applying weight extension on the fourth day, and commencing passive motion. At first the progress encouraged the hope that a false joint would be established and motion retained. After a few weeks, however, the limb began to stiffen at the hip, and all attempts at movement were so painful that I abandoned the idea of obtaining motion, and kept the limb in a straight or nearly straight position for bony anchylosis, which took place, the man obtaining a very useful limb. At the present time this man is able to walk any reason-

[1] British Medical Journal, December 24, 1870; and also a pamphlet, "A New Operation for Bony Anchylosis of the Hip-joint;" London, 1871.

able distance without stick or crutch, and earns his living by an active occupation. I have mentioned the details of this, the first case, because it very fairly represents the general course of events in others.

Deviations in several respects will have to be made in particular cases; for instance, the exact point of puncture and the direction of the same will require to be varied in reference to the altered relation of the thigh-bone to the pelvis, *i. e.*, whether the thigh is simply flexed upon the pelvis, or flexed and adducted, or abducted. The altered direction of the neck of the bone, thus produced, must be very carefully calculated by the surgeon before making the section, which should be at right angles to the long axis of the neck; great care must be taken to avoid cutting obliquely through the neck, or in a direction parallel with the shaft of the bone, a mistake easily committed if the altered direction of the neck and shaft of the bone be not carefully considered. A good general direction in the majority of cases seems to be to place the saw, just before commencing the section, parallel with Poupart's ligament, and from three-quarters of an inch to an inch below it. I have found in the dead-house that this direction will generally enable the operator to cut through the neck a little below the articular margin of the head of the bone.

Then with regard to the number of cases which have been operated upon up to the present time, and their results: I possess the records of twenty-four cases, including five operated upon by myself; four by Mr. Bryant, of Guy's Hospital; two by Mr. Sydney Jones, of St. Thomas's, and one by Mr. Croft, of the same hospital; two by Mr. Jessop, of Leeds; two by Mr. Lund, of Manchester; one by Mr. Hardie, of Manchester; one by Mr. Maunder, of the London Hospital; one by Mr. Willett, at St. Bartholomew's; one by Mr. Jowers, of Brighton; one by Mr. Furneaux Jordan, of Birmingham; one by Mr. Jonathan Hutchinson, of the London Hospital; one by Mr. Brodhurst, at St. George's, and last, but not least, one of the best and most successful, in which motion has been retained, by Dr. Sands, of New York. Out of these twenty-four cases only one death, from pyæmia, has occurred, and that in an extremely unfavorable case, in a very strumous boy, aged eight years, operated upon by Mr. Croft, at St. Thomas's Hospital. In another case, the last operated upon by myself, deep-seated, chronic suppuration followed and gradually exhausted the powers of the patient, a very strumous girl, aged eighteen years, who died eight months afterwards, having suffered from albuminuria and phthisis.

Such a result bears good testimony to the general safety of the operation, and although the dangers even of subcutaneous sections much increase with the magnitude of the operation, these may be kept within their narrowest possible limits by the judgment of the operator in selecting his cases, and the skill shown in the performance of the operation.

With regard to the selection of cases there can be no doubt that the most favorable are (1) Cases of rheumatic anchylosis, because, in rheumatism, no destruction of bone ever exists, and the head and neck of the bone always remain of their full natural size. (2) Cases of anchylosis after pyæmic inflammation, more especially in its subacute form, from which the patient generally recovers. In these cases destruction of bone rarely if ever exists, the cartilage only being more or less destroyed. (3) Cases of anchylosis after traumatic inflammation, in healthy adults, such as follows wounds of the joint, and gunshot wounds in the neighborhood of the joint. As a general rule, in these cases, little or no destruction of bone occurs even after acute suppurative inflammation. (4) The most

unfavorable cases for operation are those belonging to the strumous class, because, as a general rule in these cases, disease of the bone, with destruction of the head and neck of the thigh-bone, to a greater or less extent, takes place; and consequently, in the worst forms of this class, the operation either cannot be performed, or would be attended with such difficulties that it should not be attempted. In many cases of anchylosis after hip-joint disease in children, however, especially those in which there is little or no evidence of a strumous constitution, and in which the disease has been arrested in an early stage, without the occurrence of suppuration, not more than superficial caries exists, and sometimes the mischief is limited to the articular cartilage. In these cases the head and neck of the femur may be but little altered in form and direction, and the operation can generally be performed; and Mr. Bryant, of Guy's Hospital, has especially extended the operation with the most marked success to this class of cases.

Originally my idea was that the operation should be limited to cases of bony anchylosis, generally occurring in the adult; but the ease and safety with which Mr. Bryant has performed the operation in children from eight to fifteen years of age, will induce me also to operate in similar cases.

When the operation of dividing the neck of the femur cannot be performed in consequence of extensive destruction of the head and neck of the bone, then the operation first performed by Mr. Gant at the Royal Free Hospital in London, on December 10, 1872, should be adopted. It consists in dividing subcutaneously the shaft of the femur just below the small trochanter. The bone is cut from without inwards, and not always completely through, a portion of the femur on the inner side being broken. Instruments similar to my own are used. Mr. Gant has twice performed this operation with success.

Mr. Maunder, of the London Hospital, has also operated subcutaneously, or nearly so, in the same situation, but has substituted a chisel for the saw—as, it appears to me, without any advantage—the small saw being the more manageable instrument, and never more than one introduction being required. Mr. Maunder has, however, very successfully employed this method in several cases.

The conclusions to which, I believe, we are justified in arriving from what has been stated are—

I. That bones can be divided subcutaneously like tendons; and that the operation of completely dividing the neck of the thigh-bone by a small saw, introduced through a small subcutaneous puncture, is a well-established surgical operation attended with very little risk.

II. That the long bones can be completely divided by the same method in any part of their length with very little risk.

III. That in a large proportion of these cases the healing of the wound takes place by the first intention, and that no swelling, redness, or inflammation follows. These cases of subcutaneous osteotomy proceed as favorably as subcutaneous tenotomy.

IV. That in some cases a little suppuration from the track of the wound, amounting only to a few drops in the day, does occur for a week or more after the operation.

V. That, in a very few cases, deep-seated suppuration occurs; but in only one of these, so far as at present known, has death resulted from pyæmia out of the twenty-four recorded cases. In one other case death

was accelerated by the operation, or rather by the prolonged suppuration which followed. The patient died eight months afterwards from albuminuria and phthisis.

VI. That the permanent result of the operation has hitherto generally been to correct the deformity, and obtain bony anchylosis with the limb in a straight position; but in several instances free motion has been obtained, and remained only for a few months, when it has been gradually lost. In a few cases free motion has remained for about a year, and we hope will be persistent through life; but time and further experience are necessary before this can confidently be stated to be a reliable result of the operation.

Discussion on Mr. Adams's Paper.

After the reading of the preceding paper, Dr. Alfred C. Post, of New York said:—Many years ago I performed Dr. Barton's operation upon a young man who had had coxalgia resulting in anchylosis in such an abducted and flexed position that the genitals were hidden from view. I divided the neck of the femur, according to Barton's plan, but on the second or third day the limb became emphysematous, gangrene followed, and the patient died. At the post-mortem examination, the femoral artery and vein were found hooked over the sawn end of the bone. Such an accidental complication would not be likely to occur again, but Mr. Adams's plan of dividing the bone within the capsule would certainly avoid it.

Dr. Leopold Servais, of Belgium said:—Anchylosis may result from various causes, such as rheumatism, scrofula, syphilis, wounds, etc. The use of an anæsthetic is necessary to distinguish between true and false anchylosis. I am of the opinion that true anchylosis does not occur save in cases in which suppuration has taken place. When it is necessary to divide the femur below the trochanters, it is, I think, better to employ brute force, and break the bone, as we then have but a simple fracture to treat. From experiments lately performed in France, it has been proved that the femur is weakest at this point, and consequently it will be likely to give way there. The breaking is not difficult, as I have ascertained by fracturing the femur accidentally in other operations.

Dr. Lewis A. Sayre, of New York, said:—I would ask Mr. Adams when he begins extension, and how long he continues it?

Mr. Adams said:—I have heretofore applied extension on the fourth day, but shall in future be disposed to employ it at an earlier period. It should be continued about as long as for an ordinary fracture, but, after a few weeks, passive motion should be practised, and this should be continued once a week, under chloroform, for a long time, in order to prevent the anchylosis which is so liable to follow.

Dr. Sayre said:—The cases upon which I operated are fully reported in my book. One was the case of a female whose legs were so crossed as to interfere with micturition. I took out a section of the bone, rounding off the surfaces, and allowing the psoas and iliacus muscles to retain their attachment to the lesser trochanter. The recovery was perfect, and, when the patient died from other causes, a ligamentous connection was found to have been formed between the resected parts, and there was also a Y-shaped ligament and a form of membrane resembling the synovial. The results of my cases have been good, but I am decidedly in favor of Mr. Adams's operation, as the more simple and safe one, provided anchylosis does not subsequently occur. Mr. Adams's statement confirms my opinion that this result is quite probable, yet the cases in which it does not take place are sufficiently numerous to make the operation a desirable one. I shall in future use this method, but shall apply

extension at once, and make passive motion frequently. A divided bone, tendon, or fascia, should be at once put in proper position, as the effused lymph, being poorly vitalized, does not bear the process of subsequent stretching at all well. The danger of extending the muscles beyond their original length, and consequently separating the bones, although possible, yet will not deter me from putting on extension at once.

Dr. T. G. Richardson, of New Orleans, said:—I recall a case in which I fractured the neck of the humerus in trying to reduce an axillary dislocation of long standing. I at once pushed the broken bone up into the glenoid cavity, bound it firmly in place, commenced motion on the third day, and secured a good and movable joint.

Dr. E. M. Moore, of Rochester, said:—Dr. Bly, of Rochester, has made some experiments upon the extensibility of living muscles. He has found that the force required to stretch a muscle is very great, but that a weight of 300 lbs. will cause decided lengthening. The practical inference is that too great extension should not be used after Mr. Adams's operation, lest the ends of the bone be drawn too far apart.

REMARKS UPON PENETRATING WOUNDS OF THE ABDOMEN, WITH THE SUGGESTION OF A CHANGE OF PRACTICE IN SUCH CASES.

BY

L. A. DUGAS, M.D., LL.D.,

PROFESSOR OF SURGERY IN THE MEDICAL COLLEGE OF GEORGIA.

PENETRATING wounds of the abdomen are full of interest to the surgeon, not only because of their frequency, but also because of their extreme fatality. The marked susceptibility of the lining membrane of the abdominal cavity to morbid action, and especially to the absorption of deleterious agents, together with the importance of the organs contained, will account satisfactorily for the gravity of these wounds.

But the danger of these injuries varies according to their character and to the organ implicated. It is, therefore, not a matter of indifference whether the injury be a puncture, an incision, or a gunshot wound; for, while punctured and incised wounds are more liable to induce hemorrhage, they heal more readily by first intention; whereas gunshot wounds are less apt to be attended with serious loss of blood, but will almost invariably be followed by suppuration. In penetrating wounds of the abdomen, our first concern then is with regard to hemorrhage, which itself will depend upon whether a large vessel be opened or a parenchymatous organ be injured; for punctured and incised wounds of large vessels, and of the liver, spleen, and kidneys, are usually attended with rapidly exhausting loss of blood. If the patient escape this first danger, the question presents itself as to what we should apprehend next; and the determination of this question is of the utmost importance to the patient, as his life may depend upon it.

Upon this point there exists among written authorities the most striking uniformity in the belief that *peritonitis* is the condition most to be dreaded when primary hemorrhage has not carried off the patient, and that the extraordinary fatality of these wounds is the necessary consequence of this inflammatory action, whether induced by the mechanical injury, or by the contact of atmospheric air, of effused blood, or of fecal extravasation. And yet, when we come to examine into facts, we find that the great majority of deaths occurs so early after the injury as to render such an explanation exceedingly improbable and unsatisfactory. Death, unless from hemorrhage, usually takes place within from twenty-four to thirty-six, or at most forty-eight hours after the injury; a rapidity entirely too great to be accounted for by any process of inflammation, properly so called. No true inflammation ever runs its course to a fatal termination in so short a time. Moreover, the peritoneum is not an organ of such vital importance as to render its inflammation *necessarily* fatal; and when death does attend this inflammation from other than traumatic causes, dissolution rarely takes place in less than a week.

Again, it may be doubted that the peritoneum is as susceptible to inflammation as is generally supposed. Indeed, with the light thrown

upon this subject by the multiplied operations for ovarian disease, is it not evident that the danger of a traumatic injury, *per se*, of the peritoneum has been enormously exaggerated? Is it not also true, on the other hand, that the mortality resulting from these operations has gradually lessened with the additional care taken by the surgeon to prevent the retention of blood or other septicæmic materials in contact with the peritoneum?

With these preliminary considerations we now feel prepared to advocate the doctrine that the frightful mortality of penetrating wounds of the abdomen, and the rapidity with which the fatal result is brought about, point directly and immediately to septicæmia or blood-poisoning, as the only condition at all adequate to the production of such effects; and that the blood-poisoning is the almost necessary consequence of the plan of treatment recommended by standard authorities and carried out in daily practice.

If the intestines protrude and are found to be wounded, we are advised to cleanse, stitch, and return them into the cavity; otherwise the case is to be trusted to nature, and perhaps treated by antiphlogistics with a view to prevent or to subdue peritoneal inflammation. In the mean time the blood necessarily effused, whether much or little, is left in contact with the peritoneum, rapidly undergoes putrefactive decomposition, and is as promptly absorbed. Magendie long since demonstrated the wonderful celerity with which agents were carried into the circulation through the serous membranes. But if the system may be contaminated by the retention of blood alone in contact with the peritoneum, what should we not expect from the addition of fecal extravasation. Assuredly not *inflammation*, but most rapid septicæmic poisoning. In view of the rapidity with which toxic agents reach the circulation through the peritoneum and other serous membranes, we may safely infer that the fecal poisoning begins very soon after the extravasation, and that it must have much to do with the rapid prostration so uniformly observed in such cases, and usually attributed to nervous shock.

The awful fatality of penetrating wounds of the abdomen revealed by statistical observations would seem to indicate the necessity for a change of practice, and I have accordingly been teaching for a number of years to the classes of the Medical College of Georgia the propriety of looking upon septicæmia as the paramount danger of such wounds, and of taking such steps as would be best calculated to avert this poisoning. The recent occurrence of several fatal cases in my neighborhood prompts me now to a more formal appeal to the profession for a reconsideration of the principles by which we have been governed in such cases, and to suggest that in all instances of penetrating wounds of the abdomen, in which there may be any suspicion of the existence of effusion of blood or feces into the peritoneal cavity, the surgeon should proceed immediately as follows:—

(1) Induce anæsthesia.

(2) Lay open the abdomen along the linea alba, freely enough to make a thorough inspection of the parts contained.

(3) Ligate all bleeding vessels as far as possible.

(4) Examine carefully the whole length of the alimentary canal, in order to detect any wounds, and to stitch them. If the intestinal wound be ragged, it should be trimmed down to a straight edge.

(5) In gunshot wounds reduce the channels of entrance as well as of exit through the abdominal walls to the form of incised wounds, so that

these may be closed and left to adhere by first intention. In some cases it may be found necessary for this purpose to remove the uneven track by a double elliptic incision.

(6) Cleanse the wounds and peritoneum of all extraneous materials, and close the abdominal walls with suitable sutures and adhesive plasters.

(7) Finally, control the peristaltic action with opium, and administer such nourishment as will leave least fecal residuum, as milk, eggs, etc.

As supplementary to these suggestions it may not be out of place to add that for anæsthesia I would prefer ether, as being less enervating and safer than chloroform; and that, for stitching the intestines, animal ligatures, of catgut or violin-strings, wet with an antiseptic solution, should be preferred.

These principles have been most successfully carried out by the writer and others in cases in which the wounded intestines have protruded; and yet we have allowed other cases to die simply because the abdominal wound has not been sufficiently large to permit the bowels to come into view.

If the practice now suggested be considered harsh and hazardous, I would ask what can be worse than the authorized plan, which makes *death* the rule and recovery the rarest exception? Is it not time that we should discard as groundless the fears heretofore entertained with regard to the danger of opening the abdominal cavity? No change of practice in the class of wounds under consideration can make the chances of recovery less than they are now; and I feel confident that by adopting the plan proposed we would so alter the results as to make *recovery* the rule and death the exception.

ON OPENING THE SAC IN HERNIOTOMY.

BY

FREDERICK HYDE, M.D.,

OF CORTLAND, NEW YORK.

Both Paré and Franco, when performing Herniotomy, avoided opening the hernial sac when its contents could be reduced without its division. Their practice, however, continued to be exceptional until Petit, in cases of large and adherent hernia, left the sac entire, and till Key and Preiss adopted the method as a rule in all cases. It has been held by some surgeons that Sir Astley Cooper's plan was to leave the sac unopened in all cases. We think it will be found, from his recorded observations, that the examples in which he practised and advised leaving the sac entire, were such, in the main, as he termed, "old large ruptures." In his Lectures on the Principles and Practice of Surgery, edited by Frederick Tyrrell, will be found, in his terse description of the operation of incising the stricture in the inguinal form of the disease, all the details of opening the sac to the extent of "freely exposing its contents." He says, "if the stricture be seated in the neck of the hernial sac itself, of course the division of the part exterior to it will not relieve the strangulation; in this case, the sac must be opened carefully at the upper part, only so as to allow a division of the stricture." He also alludes to the advantage of "dilating the stricture without cutting the sac itself, as it exempts the intestine from all danger of injury from the edge of the knife." He advises, too, that the sac should not be divided higher than an inch below the abdominal ring, as its division near the abdomen makes the wound more difficult to close, and exposes the patient to greater danger from peritoneal inflammation. In his description of the operation for femoral hernia, Sir Astley concludes his directions for opening the sac in these words: "We should further divide the anterior part of the sac upwards and downwards." In strangulated umbilical hernia, he says that the peritoneal covering should be cut into, and divided in the same way as when operating for other herniæ. "In very large umbilical herniæ, when strangulated, the umbilical opening should be dilated upwards without dividing the sac."

From this brief reference to the doctrines and practice of this eminent surgeon on the question at issue, it will be seen that he generally opened the sac, and that while he expressed the belief, at least on one occasion, that herniotomy without its division might become the more successful and general operation, yet through his long and distinguished professional life, it was with him an exceptional rather than a general practice.

Petit's operation, called the minor operation, was adopted by Key in its most extended application. In discussing its merits, he says that in the majority of cases, in which patients die after this mode of operation, the death is caused by peritoneal inflammation consequent upon the exposure of an inflamed or strangulated portion of bowel. He says, too, that it is not so much the wound in the peritoneal sac that disposes to inflammation, as the exposure of the bowel to conditions to which it has

hitherto been unaccustomed. He also affirms that the inflammation following the operation for hernia spreads from that part of the bowel that has been strangulated, and does not have its origin from the incision of the sac, even if there are two wounds inflicted upon it, one to expose its contents, and another, higher up, to cut the stricture. Sir William Lawrence dissents from the opinion of Key, that recorded cases are "so largely caused by the operation of exposing the intestine, and its attendant exposure to air and light, change of temperature, and handling," and says that it is the presence of the stricture which affects the parts, not like the slight violence of the operation for a few minutes only, but uninterruptedly for hours, and sometimes days, disturbing the circulation, making an impression on the intestine as if it had been tied with a string, and sometimes causing ulceration of the internal tunics, or of the bowel in its whole thickness. Here, then, is the chief issue between Key and Lawrence; the former objecting to opening the sac, not so much from the fear of wounding it, as of the exposure of its contents to new circumstances—as air and light, change of temperature and manipulation—the latter fearing the effects of the stricture, acting continuously for a longer or shorter period, with efforts at taxis, and not the exposure of the contents of a divided sac for a few moments; and declaring that under all circumstances he is still disposed to continue the practice of opening the sac, believing it to be the most safe.

Luke, who advocates Petit's, or the minor operation, in describing it, refers to the different sites and textures in which the stricture may be; gives some rules to govern the diagnosis, admitting that the girding of the parts may be found, in the inguinal hernia of the male, at any point from the internal abdominal ring to the scrotum; and adds, finally, with regard to the necessity of opening the sac, when the stricture is caused by its thick and indurated neck, that, instead of a complete opening, only the exterior tissues of the thickened, hardened neck should be incised; when, he asserts, the neck of the sac is so far dilatable that the anterior pressure of the hernial contents will allow their return by the taxis, and directs that, in case the first efforts are not successful, this partial division is to be renewed, when by repetition of the process the strangulation may be relieved without entire opening of the sac.

Chelius, after having divided the covering down to the sac, directs that it should be "cut into, and the opening of the sac increased upwards and outwards throughout its entire length." He also says that the mode of operating in which the hernial sac is not opened at all, but only the abdominal ring dilated, so as to return the hernial sac together with the intestine, is in general to be rejected, and that the not opening of the sac is to be most especially confined to those cases in which it is certain that in a recently produced, or extraordinarily large rupture, or in a rupture entirely adhering to the neck of the sac, the strangulation is seated in the abdominal ring. Twenty-five years ago, Skey, in describing the operation of herniotomy, used these words: "By proceeding slowly through the various coverings, we reach the sac of the peritoneum. Sometimes the sac is drawn so tightly over the contents as to be separated from them with difficulty. We select for this purpose the lower part, which is usually somewhat distended by gravitating fluid, and here it may be opened without danger." In the fourth American edition of Fergusson's Practical Surgery, in the account of the operation for strangulated inguinal hernia, it is directed that, after having divided all the overlying tissues, so as to lay bare the outer surface of the sac,

"a small aperture should be cautiously made in this membrane, which should then be more fully laid open." Fergusson also says that, "in large protrusions, it would unquestionably be highly desirable to return the contents without exposing the peritoneal surface. In the majority of such cases the stricture may be divided without penetrating the sac, but in some instances, even after this has been done, the protrusion cannot be returned in consequence of adhesions."

Prof. Gibson, in the sixth edition of his "Surgery" describes the manner of opening the sac as "an important part of the operation of herniotomy." He refers to the operation of dividing the stricture outside of the sac, with his objections, and directs that the sac should be opened in inguinal, femoral, and umbilical herniæ. Miller, in discussing the question of opening the sac, says, "were it applied indiscriminately, nothing could well be conceived more pernicious." In the operation for femoral hernia, he says, "usually the opening cannot be avoided." In Erichsen's description of the general operation of herniotomy, he says, "the sac, having been exposed, must be carefully opened towards its anterior aspect, and if it be a small one, at its lower part." When operating for the inguinal form, he says, "if it be found after the division of the fascia that the stricture has been removed, and the hernia can be reduced, it would, of course, be unnecessary to lay open the sac, and the safety of the patient will be considerably enhanced, and particularly if the operation is performed for an old scrotal hernia of large size, by not doing so. . . . If, however," he adds, "as will happen in the majority of instances, in inguinal hernia, it be found that the stricture is in the neck of the sac itself, it must be carefully opened." In concluding his description of the more common operation for femoral hernia, he says: "When the sac has been reached, it must be carefully opened." In umbilical hernia, the stricture should, if possible, be divided without opening the sac. He further says that the operation without opening the sac may be practised in all forms of hernia, but is much more readily done in some varieties of the disease than others. It is especially applicable in cases of femoral hernia, in which the stricture is commonly outside the sac. In inguinal hernia, it is not so easy to perform Petit's operation; indeed in the majority of cases, the surgeon will fail to remove the stricture in this way.

Thomas Bryant says: "When the hernia cannot be reduced without opening the sac, the whole must necessarily be explored." It will be thus seen that the question of opening or not opening the sac, turns upon the necessities of the individual case. After some arguments against opening the sac, he adduces some statistics in favor of the minor operation, but adds that it must be remembered that, as a rule, the cases in which the sac was not opened were of a more favorable kind than those in which it was opened. In describing his plan of operating to cut the stricture outside the sac, he says that if no indications of reduction show themselves, or if part of the contents of the sac have disappeared, but not with the characteristic jerk, or if some portion has been left behind, the sac must be opened. "In all operations for femoral hernia, the reduction of the hernia without opening the sac should be preferred, and in recent herniæ this minor operation is generally successful. Should it fail, and the sac have to be opened, no harm can possibly have been caused by the proceeding, for the incision can readily be enlarged if necessary, the sac opened, and its neck divided." In describing the procedures of herniotomy, Gross directs how to recognize the sac, and then

adds, "An opening just large enough to admit the point of the director is now made, when, the instrument being carried upwards and then downwards, the sac is divided to the required extent." Referring to the advantages and disadvantages of division of the stricture without the sac, he concludes in these words: "It would not be proper in the existing state of our knowledge to pronounce a decisive judgment upon a subject of so much importance as this unquestionably is; we must wait for further data, and in the mean time adopt the rule to lay open the proper hernial sac whenever there is any reasonable doubt in regard to the site of the stricture. Having divided all the fascial layers down to the sac, in femoral hernia, it may happen that the stricture is seated within the sac, particularly if the hernia be large and old, and, when this is the case, the sac must of course be laid open, its division being effected in the same manner as in inguinal hernia."

Hamilton writes: "The sac being fairly exposed, a small fold may be raised at its most depending point, and an opening made large enough to introduce a director, and upon this the incision may be enlarged." Division of the stricture outside of the sac, if practised, should be reserved for exceptional cases. In femoral hernia, the sac being reached, opened, and the contents examined, then follows the treatment of the stricture." He adds that division of the stricture outside of the sac is probably more often applicable to femoral hernia than to either of the forms of the inguinal variety. "In umbilical hernia," he says, "when it has been necessary to open the sac, the result has generally been fatal. It is advisable, therefore, always to attempt the reduction by division of the stricture outside of the sac."

Our object thus far has been to place, side by side, the opinions and practice of the eminent surgeons to whose names we have referred, without a recapitulation of the arguments by which their conclusions are reached upon the questions at issue. The external operation has been before the profession, at least since its earnest espousal by Petit, in 1718. It found strong advocates in Monro, Key, Luke, and some others, but had not occupied the attention of surgeons generally until near 1833. It is true that, by the English surgeons, the minor operation was first most thoroughly tested, but for a considerable period it has been more or less under consideration by surgeons in all countries. It is now more than a century and a half since it became a favorite operation with some British surgeons, and for the last thirty or forty years it has been practised in Great Britain, on the continent of Europe, and in the United States. Has the minor operation acquired for itself that reputation as an exclusive mode of treatment for strangulation which its earliest or later strong advocates predicted for it?

We think that it will be found that a majority of surgeons who advise non-opening of the sac, reserve certain conditions as incompatible with the minor operation, and admit that in those cases division of the sac is positively required. Then, again, believing the case one favorable to leaving the sac entire, but finding as the operation progresses that reduction cannot be accomplished, they finally resort to cutting the sac. Among all the surgeons who prefer the minor operation, we do not call to mind one who denies the necessity for opening the sac when the stricture exists in the latter structure.

In the statistics on this question, in which the results appear more favorable for the non-opening of the sac, it is conceded that the cases

were of a more promising character for either mode of procedure; this, we think, raises the question, whether the conditions of a case which entitle the minor operation to be preferred, can be recognized before the operation. While some of the average conditions of strictured inguinal and femoral herniæ may be pretty well determined before exposure of the interior textures, the writer's experience compels him to say that more of the important relations of the structures, as well as their pathological conditions, cannot be so well known while in this occult state. If a century and a half, or more, of well-directed surgical acumen had determined the fixed, uniform, pathological conditions in the disease under review, then could our diagnosis enable us much better to say when a strictured protrusion could be successfully reduced with its sac intact. The majority of examples of hernia, it is true, embrace primarily only definite anatomical structures; but from the first day of their history their relations are liable to change, and, with these, occur functional aberrations and structural alterations. The age of the patient; how far the disease is congenital or acquired; whether it is indebted in any way, and if so how far, to strictly traumatic causes; the site of the rupture; the contents of the protrusion; the distance it has gone from its normal home and the direction taken; the volume of the mass; accidents to which it may have been subjected; the varying of the sac from extreme tenuity and pliancy to great thickening and induration; its range of contiguous relations to either or both its surfaces; the more or less frequent transit of the contents through the abdominal apertures in either direction; and occasionally the permanent extra-abdominal situation—are some of the circumstances which will, to more or less extent, influence the case when strangulation exists, bearing directly upon its treatment, both by the taxis and herniotomy, and which will determine largely the results of the latter. The history of all forms of hernia is made up of varying conditions which we believe must contribute to pathological changes, and aid in individualizing cases to an extent to entitle each and every one to its own consideration.

These are some of the reasons why the operator cannot predict positively what are the morbid changes in a given case of the disease, as long as these are hidden from his vision. With his increased facilities for observation he is all the more certain of disappointment if he expects to find marked sameness in the pathological appearances in a number of examples of either of the leading forms of the disease, but more especially of inguinal hernia. What surgeon, before he commences the operation of herniotomy, is quite willing to specify what will be the departures from normal anatomy, either in tissue or relation, until disclosed by his incisions? While he is positive enough concerning the presence of some of the conditions, he is obliged to admit that he is doubtful of others, and these are most likely to be the important factors in the results. These ever-varying phases, sure to be present to a greater or less degree in a great majority of the examples in every variety of hernia, are never to be ignored, but carefully analyzed and considered, whatever treatment is chosen; and until we can make our diagnosis more satisfactory touching the interior state of the sac and its contents, including their true condition and relation, we shall be compelled to accept the major operation instead of leaving the sac unopened. It will be conceded by all authorities, we think, that no part of a hernial tumor or swelling is of such high importance as the contents of the sac, and that these, more than all others, are the textures both primarily and secondarily imperiled.

when strictured. These are the parts which our treatment seeks to relieve as early as possible when in this state. The taxis having failed, the girding point or points are found and divided. Has this been done outside and the protrusion returned, with or without manipulation, it may be well, it may be otherwise. This will depend wholly upon the fitness or not of the returned parts to occupy their original place in the abdomen. How is this to be known? It may be said, because the hernia was reduced so readily after the stricture was relieved. Does it follow certainly, from this ready return of the mass into the abdomen, that it was free from changes that would not permit it to remain there safely, or that it might not in this returned state prove more serious to the patient than if allowed a place outside the abdomen after the stricture had been divided? Our own observation has taught us that the readiness with which the protrusion is reduced after the minor operation is by no means reliable proof that the returned parts are in fit condition to allow recovery, as proved by inspection after death. But what does it mean when all stricturing tissues exterior to the sac have been severed, and the hernia cannot be reduced? We know no way to answer this inquiry but to open the sac and expose its contents, when, if there be any form of internal binding, it may be readily reached and overcome, and reduction accomplished or not, as the state of the strangulated parts may warrant. In the operation of herniotomy, when the sac is made bare, how far will the vision or tactile ability of the surgeon enable him to say what is the real state and relation of its contained textures? We answer for ourselves that it is scarcely more than inferred, and when we have succeeded in reducing an inguinal or femoral hernia in this way, our solicitude remains at high pitch until sufficient time has elapsed to prove that all signs of strangulation are well over.

What are the objections to opening the sac? Perhaps the one most commonly urged is, that it increases the liability to inflammation in the sac itself, and its extension along the peritoneal tissue. Allowing that this texture is readily inflamed from slight causes, we cannot see as a rule how the dangers incident to a small incised wound in the sac should be as great as those incurred by returning the bowel in its average condition, in this kind of cases. In the minor operation, provided there be no other strictured point beyond that outside of the sac, how readily are the protruded parts restored to the abdomen? Granting the usual proportion of examples of adhesions of the sac more or less to structures extra-abdominal, and that the contents are in a state to move freely within the sac, then we think that the manipulations requisite for reduction having to be made through the walls of the sac, the whole depending upon the touch, are so much embarrassed that much greater risk of injury is incurred than by the wound necessary to bring at once into view the true state and relation of the already, it may be, highly sensitive contents. Again, when we think we succeed well in returning the contents wholly into the abdomen, in cases of adherent and hypertrophied sac walls, by careful watching, we may well doubt whether there may not be some portion of intestine not quite within the abdomen. We remember that more or less exudation has occurred during the period of strangulation, and that a fold or process of intestine or mesentery, or even a portion of omentum, may easily enough, in the midst of the more or less plastic effusion, adhere both just below and quite within the upper aperture, and so cause an incomplete reduction. In these examples much of the fulness may disappear, leaving only so much as can well be explained by

the firm thickened sac, with often a marked feeling of relief so expressed by the patient, but soon to be followed by an exacerbation of the symptoms of strangulation. Under most circumstances, our choice would be to accept the risk of an incised wound in the hernial sac, rather than too long trial of the taxis before the coverings have been divided, or its application in the average state of cases after the stricture has been cut without dividing the sac. We cannot see how a wound in the hernial sac is likely to be followed by more inflammation, or any more serious results, than a wound of the same tissue in any other place, beyond what would be inevitable from the already morbid state of the within and adjacent structures. When we call to mind how rare an event it has been, in the clinical history of the operation in question, that incising the hernial sac has added to the inflammation, or contributed in any possible way to the untoward results of the case, we declare our conviction that in a large majority of examples of inguinal and femoral strangulation, the major operation is the safest. We put the question to all surgeons, whether their cases of herniotomy which have been fatal, have not been so from morbid changes already present before the division of the sac and stricture?

Another objection to this operation of opening the sac is, that it exposes the contents to accession of air and light, with change of temperature, suddenly creating new relations which cannot be tolerated. We cannot understand why the peril should be any more by the exposure in this operation than in others in which a much larger portion of the peritoneal surface, with a far greater amount of visceral texture, is suddenly brought in contact with the atmosphere, as amply illustrated in the operation of ovariotomy, and other constantly occurring examples of traumatic lesion of the abdominal textures. We believe that in a large majority of instances, neither the liability of adding an increase of inflammation by opening the sac, nor that of multiplying dangers by the exposure to the air and light for a few moments, of the interior textures, will add as much to the dangers as the untoward manner of applying the taxis with the sac-wall entire, together with the great liability to unfitness of the contents for a safe restoration. If it be said that the views inculcated in this paper are at variance with a commendable spirit of surgical conservatism, then we affirm our belief that it is a much more conserving practice to expose by a well made incision the real state and relations of the suffering tissues, by which every subsequent step for relief can be aided by direct vision, than to adopt a procedure which must be mainly directed without the aid of the surgeon's eye, and commonly, if it effect reduction, requiring a more protracted tactile labor, and always involving the risks of unrelieved strictures, and too often of structures returned to the abdomen, which should have been left outside. The writer, restricting himself to only the authentic clinical histories of a considerably large number of cases, with their results, in which both non-opening and opening the sac were practised, and to the pathological facts furnished by autopsies in a majority of the fatal cases, cannot truthfully arrive at any other opinion than the one already expressed. It must be admitted that there are many surgeons whose opinions are entitled to the highest respect, who would not adopt the major operation as exclusively as we have indicated. The writer regrets to say that he has met with more hindrance than he had anticipated in obtaining from surgical practitioners their individual experience upon the respective merits of the operations in question. It is the honest difference of senti-

ment among surgeons which has chiefly led the writer to call attention to this very important practical question, so that if he cannot reflect new light upon his theme, other surgeons may be induced to make a more free declaration of the results of their experience upon this important subject through the legitimate channels of communicating professional truth.

From what has been said, we conclude—

I. That the examples in which the minor operation is most successful are those but slightly removed from a condition permitting reduction by the taxis, and that the length of time during which strangulation has existed is not of itself the true measure of the condition of the strictured parts, these often presenting more morbid changes when strangulated but a few hours, than in other instances of days' duration.

II. That cases which furnish the most favorable results from the minor operation, are also the most promising for opening the sac.

III. That there are many cases of strangulation in which the stricture cannot be relieved without division of the sac.

IV. That our means of diagnosis are insufficient to enable us to say, in a vast number of cases, whether the strictured parts are in a suitable condition to be returned to the abdomen while the sac is entire.

V. That a due regard to the credit of herniotomy, when every variety of inguinal and femoral strangulation is included, requires that the major operation should be adopted in a large majority of patients in this condition.

VI. That opening the sac in strangulated umbilical hernia is not to be practised if reduction of the protrusion can be accomplished without it.

SOME COMMENTS ON THE HISTORY OF NITROUS OXIDE GAS AS AN ANÆSTHETIC, AND ON THE ANALGESIC EFFECTS OF RAPID BREATHING.

BY

ADDINELL HEWSON, M.D.,

SURGEON TO THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

It would seem impossible that a suggestion of such a practical character, of such immense value to mankind, and made by such authority, as that proposed by Davy of using inhalations of a gas to destroy pain in surgical operations, should go absolutely unheeded for nearly half a century, and yet such was really the case; for Sir Humphry Davy, in a publication, in 1800, of "Researches, Chemical and Physical, chiefly concerning Nitrous Oxide and its Inspirations," suggested from inhalations of that gas made by himself and others that "as nitrous oxide in its extensive operations appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." This suggestion he never recalled or condemned during his subsequent brilliant career, when everything emanating from his fertile brain was sought after and followed with avidity and zeal. There was no pretext of want of desire for such a means; the practice was almost universal of resorting to the effects of alcohol and opiates to deaden and as far as possible destroy the sensibility to pain during operations. The evil effects of the latter practice were also fully recognized, and yet, as I have said, this proposal of Davy was absolutely allowed to go unheeded and to become forgotten, for, when Dr. Horace Wells, a dentist of Hartford, Connecticut, in 1844, thought of using nitrous oxide gas in extracting teeth, no one was then ready to condemn it on the ground of previous failures, or because it had been proposed so long before.

Wells's idea would seem to have arisen in his own mind on witnessing an effect of the inhalation at a public exhibition given by a travelling lecturer. On this occasion, one of the persons to whom the gas had been administered, whilst under its influence, struck his foot, and on recovering his consciousness it was discovered, by Wells's inquiries, that he had sustained a severe bruise without being aware of it from any pain at the time. This fact led Wells to the inference that the gas could produce insensibility to pain, and he determined to test this by having a tooth extracted while under its influence. The lecturer was invited to his office to administer the gas, and during this administration Wells had the tooth drawn without experiencing any more pain than is produced on a person in a state of perfect consciousness by the prick of a pin. This result led Wells to pursue the subject further; he tried the effect of the gas in a number of cases of tooth extraction (about fifteen), but with varying success; he then went to Boston and got permission from Dr. Warren to make a demonstration of the process in tooth-pulling before the class of the Massachusetts General Hospital. This attempt was an

utter failure, and was called "a humbug affair." Wells went home, told his friends that the gas would not operate as he had hoped, "and wholly ceased to experiment from the date of his failure in Boston (in December, 1844), until the spring of 1847."[1]

In the interval between these two periods, complete demonstration had been made by Morton, his former partner in dentistry, of the power of the vapor of ether to produce the desired insensibility. Morton had no doubt had his zeal to discover some such agent excited by Wells's previous successes; he would appear to have been impressed with the idea that these were essentially the effects of imagination on the part of the patient, for on September 30, 1846, he went to the laboratory of Dr. Jackson, whom he knew well, having been a student under him and recently in his house, and took from a closet an India rubber gas bag. In reply to an inquiry of that gentleman, he said in substance "that he meant to fill the bag with air, and by its aid extract the tooth of a refractory patient." A conversation ensued upon the effects of the imagination and, among other things, of nitrous oxide, in producing insensibility.[2] Jackson treated Morton's proposition lightly; he told him to go to an apothecary and procure sulphuric ether—the stronger the better—which would produce the insensibility he desired. The ether was to be spattered on a handkerchief and inhaled; in a moment or two perfect insensibility would be produced. "Sulphuric ether," said Morton (so goes Jackson's account), "what is that; is it a gas? Show it to me." Jackson said he showed him some ether, and, after further conversation, Morton went to procure it.[3] Morton and his friends subsequently claimed that his expressed ignorance of ether at this interview was merely assumed, to prevent Jackson from setting up any claim to participation in his own search for painless dentistry. He showed by the testimony of Dr. Gould and of Messrs. Weightman and Metcalf, that he was before this time a dentist who was experimenting upon the relief of pain in dental operations, and that he was familiar with the properties of ether. Not only so, but by subsequent experiments he proved that to be certain and safe which may have been thought by others previously to be a possibility.

Morton possessed traits of character essential for success: he was earnest and persevering beyond conception, as we are told by Professor Bigelow, who was personally acquainted with him, a participator in many of the steps in the early progress of the discovery, and who did much to bring it before the medical public of this country and of Europe, to assert its real value, and to point out the best methods of utilizing it.[4] Morton possessed these traits to an extent evidently far greater than his former partner, Wells, for, as I have before stated, the latter, disheartened and discouraged by his failure at the Massachusetts General Hospital, abandoned his investigations and searches "for more promising enterprises." When Morton had got sufficient confidence by his trials with ether, he went, like his partner, Wells, to the Massachusetts General Hospital, in October, 1846, and made a demonstration there of his process. This demonstration was an eminently successful one. Within two weeks the whole world was ringing with wonder at the discovery.

[1] Bigelow's History of the Discovery of Modern Anæsthesia, American Journ. of Med. Sciences, Jan. 1876.
[2] Bigelow, loc. cit., p. 171. [3] Ibid.
[4] Gross, Century of American Medicine, Am. Journ. of Med. Sciences, April, 1876.

By many its possibility was denied; by others it was ridiculed; by others its claim to originality was attempted to be ignored; and, finally, it was preached against from the pulpit, as I heard myself, as being, in one of its proposed applications, viz., to midwifery, an attempt to defy the orderings of the Almighty.

Morton, at once, on his first success at the hospital, seeing in the thing a source of great profit, wrote to Wells stating that he was about sending out agents to dispose of the right to use his discovery, and offered him an agency on shares. Wells, in his answer to this letter, says, "If the operation of administering the gas is not attended with too much trouble and will produce the effect you state, it will undoubtedly be a fortune to you, provided it is rightly managed."[1] Here the question may very naturally arise: Have we not in this answer of Wells a clue to the causes of his abandoning his searches after anæsthesia? The administration of nitrous oxide was "attended with too much trouble," and he had not rightly managed it to make it "a fortune" to himself; for our (the medical) profession must not in judging of the conduct of two members of another (the dental) profession overlook the fact that the latter consideration can be entertained by them and not by us. The former consideration, that of "too much trouble," had no doubt always been in the way of using nitrous oxide, from the day of Humphry Davy's proposal to that of Wells's abandonment of the idea. It was indeed an obstacle to the general use of ether, at first, for then it was supposed that it could not be confided to any but an experienced administrator for whose service an extra charge had to be made.

Morton's demonstration that the secret of success with ether lay in the full quantity of the vapor used was slow in being recognized, and the dread of fatal asphyxia was so predominant in the minds of the majority of practitioners, that for many years after the introduction of anæsthesia the fact of its being unsuited to a large number of cases (other than those of heart and lung disease) was considered to be beyond all question. The partial recognition of this secret with ether, led many (and possibly Wells amongst them) to the idea that the failures with nitrous oxide had been from the insufficiency of the amount used. The "traditional exhilarating gas bag and Davy's exhilarating dose were what had heretofore been used, and they were inadequate to produce anæsthesia with any certainty."[2] The first demonstration of this fact was in a breast excision performed by Prof. Bigelow at the Massachusetts General Hospital, in April, 1848, by means of about sixty gallons of gas.[3]

This, however, did not give nitrous oxide its true position as a so-called anæsthetic agent, as for years afterwards it was ignored entirely. This may have been from the enthusiasm which existed for ether and chloroform (for the latter was proposed by Prof. Simpson, of Edinburgh, in 1840), and yet the "too much trouble" in its administration also undoubtedly exerted an influence against nitrous oxide. It was in fact nearly nineteen years from the time of Wells's first experiment until G. Q. Colton, the same lecturer who had administered the gas to Wells on that occasion, recognizing its real value and that the secret of its success lay in an abundant use of it, secured the aid of a competent extractor of teeth and then made it known as a safe and popular agent in

[1] See Morton's letter of Oct. 19, and Wells's answer of Oct. 20, 1846.
[2] Bigelow, loc. cit.
[3] Ibid., p. 168.

painless dentistry.[1] Before that time dentists advertised frequently "to extract teeth under ether," or "to administer sulphuric ether," or "chloroform," but no one thought of or used nitrous oxide. It was said "not to be as successful as ether;" "not to be a safe agent;" "to be more troublesome;" but since Colton's successes we have "nitrous oxide gas administered" advertised on a host of dentists' windows, and those dentists who do not administer it themselves, do not hesitate to send their patients to establishments gotten up exclusively for that purpose—many of them designated as "Colton Institutes" in recognition of what Colton did to popularize the matter. More than this, since then, the surgical profession has recognized the advantage of the use of nitrous oxide gas over ether in a great variety of the minor operations of surgery, notwithstanding the inconvenience from so much trouble in its administration. Hosts of surgeons have experienced the annoyances and inconveniences of using ether or chloroform in their office practice, from the "post prandial" effects of those agents, and recognizing the absence of such with nitrous oxide gas, have since then availed themselves with avidity of the proximity to their own offices of a "Colton Institute," or of an administrator of nitrous oxide gas, to employ the gas in many cases of ophthalmic surgery or of operations of short duration which they could perform in their offices without detriment or inconvenience to their patients, provided that they could do them in a painless way.

I confess myself to have been a full participator in this feeling, and yet this was from no want of appreciation of the value of ether or chloroform; all who have known me have always been aware of my being a most enthusiastic friend to these agents, and especially to ether. I was as a student a witness with my father of the first public demonstrations of the use of ether in Philadelphia. He was at that time the honored president of our most venerable medical society; he had held that position for over twelve years, and was over seventy-three years of age, and yet he was a most zealous student, always ready to adopt any measure which held out a prospect of alleviation to the suffering of his patients; but he was also possessed with the prudence and caution common to such advanced years, and of this I had the full advantage in hearing his comments after each clinic, and his discussions with his friends at home. He had been educated in England before Davy's proposal was made, when the practice of resorting to intoxication by alcohol and opium, as a preliminary to major operations, was very common, and he was not slow at the time to which I have referred to perceive the relations of these with ether and chloroform in the cyanosed or carbonized state of the blood produced by them; and he considered the state caused by the inhalation of ether as one of greater inebriation than that produced by alcohol. He therefore argued that the vapor of the former should be applied persistently until that extreme state was brought about, but not so abundantly or exclusively as to induce a state of asphyxia.

Such a view then (my father died in 1848) was far in advance of that held by the practitioners of that day. The cyanosing of, or retention of carbonic acid in, the blood, was then looked upon as an accidental and unfortunate circumstance in a case, and I therefore refer to his view as an evidence of the advanced schooling I had on the subject. My zeal for the use of anæsthesia whilst a student on one occasion subjected me to what was meant to be a severe censure before a class of fellow students. It

[1] See Thomas's Manual on Nitrous Oxide, p. 17.

was on the occasion of prolonged efforts of over two hours to reduce a dislocated hip-joint at the clinic of one of our most conservative institutions, and when whiskey and laudanum had been most freely used; several of the class, myself amongst them, had been asked to lend a hand at the pulleys, and we had all failed. I, on failing, said *sotto voce*, to the surgeon, "Doctor, why don't you give him ether?" And he turned round in a most excited manner to the class of nearly two hundred students, and exclaimed, "Gentlemen, one of your number asks me why I won't give this man ether? I would as soon cut his throat." Within twelve hours after this, the ether was given to the man, and his hip reduced, apparently in a moment of time; but I, as an interloper, was there amongst a few to witness the result.

For the past twenty-four years, as a hospital surgeon in Philadelphia (at the Hospital of the Protestant Episcopal Church, at Wills Hospital, and at the Pennsylvania Hospital), I have never lost an opportunity of using anæsthetics, and no one can, therefore, even insinuate that I have been wanting in appreciation of their value. In private practice I have used freely ether, chloroform, nitrous oxide gas, and local anæsthesia (by the atomizer, and by ice and salt and kindred articles), and yet I am free to confess, as I said before, that I have longed for some easier method, or some method free from after annoyances, with which I could save my patients, especially in minor operations or physical explorations, from pain. It is, therefore, very certain that I most gladly availed myself of Dr. Wm. G. A. Bonwill's first suggestion to me that simple rapid respiration would produce insensibility to pain, if prolonged for from three to five minutes, and carried on in as rapid a manner as possible during that short space of time. I tried it first in a case of necrosed femur, where there was a state of great hyperæsthesia, and where I was particularly desirous of avoiding the production of pain; and when (in my office) I did not want to resort to ether or the like. Here I had most perfect success, using the probe freely with the sounding-board appended to it, and still causing my patient not a particle of suffering. I repeated the experiments with like cases in the wards of the Pennsylvania Hospital, then tried the procedure in other minor cases, but not always with the satisfactory results that I obtained in the first of them; the failures, however, were not such as to deter me from the further pursuit of the subject.

My former experiences, with the first attempts at anæsthesia with ether, were such as not to suffer me to become disheartened here. Who is there, who went through the early history of ether, who cannot recall, as I before intimated, the many failures to produce complete insensibility with that agent then, which would not be suffered to occur at the present day? It was then a novelty, and those who used it were ignorant of all the essentials for its invariable success. Such I felt was the case with my experience with rapid respiration; I had a good deal to learn even in what looked like a very simple affair, and seemed to require no experience or even judgment in its use. My first attempt to demonstrate its value before the class at the Pennsylvania Hospital showed this very clearly. I then had brought into the clinic room two boys for explorations with the probe, on whom I had tried the process in the ward with most satisfactory results. The first one of these was remarked by me at the time before the class as "a bright little fellow, who looked at me very cheerfully on that day, and in this respect was very different from what he had been at the beginning of our interviews

some days before;" he then had dreaded the probing. He had been before the class more than once, and had had on one of those occasions ether administered for an exploration by my predecessor, who then uncovered the tibia by a free incision, and, demonstrating most clearly its necrotic state, removed a large portion of it by the chisel and forceps, aided by the trephine. The little fellow, on the occasion of my lecture, espied, as he came into the room, the ether bottle and a lot of instruments on a side-table, and nothing could induce him to believe that it was not my purpose to deceive him, and to perform some operation with the instruments when he should become insensible. He, however, started to breathe rapidly, but kept glancing constantly at the table till I had it removed out of his sight; but his dread was too predominant; he began to cry, and finally positively refused at all to breathe with any exertion or rapidity. I left him and turned to the other boy, who had never been in a clinic before; but he, participating in his companion's dread, followed his example, evidently for the purpose of making a like escape from having anything done with his case.

The reporter of my lecture on this occasion, Dr. T. H. Bradford, one of the residents of the Pennsylvania Hospital, then volunteered to try the process before the class. "It was his first attempt, and was made sitting erect, with his right hand resting upon a table. Breathing rapidly was attended first with a tingling sensation of the surface, especially of the fingers, and a feeling as though the surface was all swelling. Then (in about three minutes of time from the beginning) there followed a dizziness or compression in the head, with consciousness well preserved, but with a feeling of inability to resist, or to act in an independent way." I had directed this gentleman, before he showed the least sign of loss of sensation or consciousness, to raise his left hand as soon as he felt me touching him on the right. At this point, when he began to become cyanosed, he raised the left hand, and, continuing the motion, got to swinging the limb from the shoulder, much to the amusement of the class, and so afforded a very positive proof that he was not perfectly himself. In the continuation of his report,[1] he says: "He remembered well being frequently asked by [me] the doctor, if he was hurting him, but had no recollection afterwards of the pin sticking him, much less of its having been firmly imbedded in his flesh, as he found it when he had ceased the rapid respirations, and the anæsthetic effect had passed off."

The failure with the two boys was clearly the result of emotional excitement and want of will on their part; obstacles to success readily anticipated in any such attempt, but which do not present themselves now in the use of ether, chloroform, or the like, for with them we do not hesitate to, and can, compel the patient to take the anæsthetic; we are independent of his will; but such was not considered to be the case with those agents when they were first used. It was then thought necessary to have co-operation from the patient. I saw many a case in the early period of anæsthesia, where the attempt was abandoned for want of this. It is not at all possible that we shall ever be so independent with rapid respiration. Confidence in its success will, however, as it has done already with me and my patients, diminish the frequency of such a cause for failure; I have profited well from this part of the lesson of that day. But the failures then also gave me, by the opportunity with my assistant, to see that *complete anæsthesia* was not to be sought

[1] Medical Times, March 4, 1876.

by such a procedure, and likewise, very positively, that it was not essential for our purposes, for it must be remembered that I was not in search of an *anæsthetic* agent to supersede those like ether and chloroform, but one most convenient to destroy the sensibility to pain, and that alone.

The destroying of pain merely was certainly more desirable than the state of full anæsthesia from ether, with its accompanying loss of all consciousness and will. Appreciating this advantage, then, from the rapid respiration, I had the opportunity at the following clinic of demonstrating it in a most satisfactory manner. During that clinic it was announced to me that a man was in the receiving ward—had just come in—with, it was supposed by the nurse, a dislocation of his shoulder. Without going to make any preliminary examination, I directed him to be brought before the class. As he came into the clinic room, I called the attention of the class to his carriage; to the manner in which he supported the injured limb at the elbow, by the other hand; to how he leaned forward on that side; and to how the shoulder was depressed and the elbow projected away from the body—all affording very good grounds for the supposition that his shoulder was dislocated. When he was stripped, these appearances were still more marked, and during the undressing he seemed in great pain. Then I announced to the class that I would proceed to demonstrate the existence or non-existence of dislocation without inflicting any further pain on the patient, and without touching him. I then directed him to breathe rapidly, assuring him that it would remove his pains. He did it promptly, and in the usual time began to show its effects. I then told him to raise the hand of the injured limb and place it on his head. This he did without any signs of suffering. Then, whilst he was still urged to keep up the rapid breathing, he was directed to place the same hand on the opposite shoulder; then down by his injured side; and finally behind his back. All these movements he made, sluggishly it is true, but with an absence of all indications of pain. I, of course, then made free comment on the advantage we could have in all such cases with this mode of destroying pain, over that by ether or the like.

This condition of "insensibility to pain with conservation of intelligence, of consciousness, and of voluntary movement," recognized by recent authors, by the term of *Analgesia* (from α, privative, and αλγεω, I feel pain), in contradistinction to the loss of all these conditions to be designated by the generic term of *Anæsthesia*, or what I called a few moments ago complete anæsthesia, was shown at the French Academy of Sciences, in March, 1872, by M. Guibert, to follow the *partial* use of chloroform inhalations, some time after a hypodermic injection of morphia; and he then advocated the state as sufficing for obstetrics and minor surgery. The non-recognition of the occurrence of such a state, or the want of appreciation of its value for such purposes, has, I know, led many to condemn a resort to rapid respiration; and then again, many perceiving the preservation of intelligence, of consciousness, or of voluntary motion, have condemned the process as incapable of producing insensibility to pain. They have evidently not been aware of the researches of Bernard, Guibert, and others in England, as well as in France, on this subject. The fortuitous experiment with my assistant, Dr. Bradford, as I intimated before, was the first circumstance to open my eyes to the value of the distinction. With the use of ether, and the like, I was always accustomed to look for perfect insensibility of the conjunctiva as evidence of my patient being fitted for me to begin any operative

procedure. With that condition we all know there is always the perfect loss of those mental and voluntary conditions which belong to complete anæsthesia. (The combination of a previous hypodermic injection of morphia with the anæsthetic, as suggested first by Bernard, holds out no inducement for a resort to such in the cases to which I have been referring.)

In my earliest trials of insensibility by rapid respiration I had not thought of Guibert's distinction of the two states. In many of these the object was to avoid suffering in trifling operations—operations strictly of minor surgery; but, after Dr. Bradford's trial, I could not refrain from seeing its value beyond cases of dislocation, even in really major operations about the pharynx, on the tonsils, uvula, posterior nares, and Eustachian tube, as well as on the tongue and maxillary bones; for in these the anæsthesia from ether and chloroform, when attempted to be used, has always to be abandoned (particularly in the most extensive of them) on account of danger of strangulation from the absence of any volition by which the patient can expel the blood from the mouth. The mode of effecting insensibility to pain by rapid breathing is also not at all in our way as we proceed in these operations, which cannot be said when ether is used. In such cases we can, as I know from experience, also keep up the insensibility produced by rapid breathing to the end of the operation, even when there are frequent and prolonged interruptions from hemorrhage, by urging the patient, immediately after or during such, to blow out as rapidly as possible. In some such instances I have noticed the patient, either impressed with the advantages or acting mechanically as some would suppose, carry on this breathing most earnestly until assured there was no further necessity for it. Here we have also another advantage: we can always stop the procedure. I have never seen a case in which I could not, and have, therefore, in instances where it became desirable to interrupt the insensibility, always effected it very readily; and this advantage is a very great one even in other cases than those of operation about the air-passages. Thus, for instance, as Guibert says, analgesia has advantages for obstetrical cases. I have in my own experience seen the advantage of this breathing process, not only in the insensibility with co-operative action on the part of the patient in ordinary labor cases, but also in the facility of terminating it, as, for instance, in the supervention of flooding where it becomes desirable to remove all causes of muscular relaxation, which cannot be done immediately where other processes of insensibility have been used. Here I know that I have been able to save patients' lives, where I feel, in these special cases, it would have been impossible to do so if they had been under the influence of ether or chloroform. All instrumental labor, as I know, can be carried on with perfect satisfaction under this process.

Most operations about the uterus, the vagina, the bladder, and the rectum, are also disarmed by this process of one of their terrors to the female, as they cannot be as surely in the case of ether or the like, viz., that of unnecessary exposure. I have frequently, in the past year, dilated the uterus by an Atlee's or Ellinger's dilator, straightened and replaced it, explored it by a Simpson's sound and other means, dilated the vagina by a trivalve speculum, and dilated the urethra and rectum, in the former of these last two instances to the extent that I could pass my index finger into the bladder, and in the latter so that I could pass three or more fingers into the bowel, with my patient lying quietly on her left side (in the ordinary obstetric position), evidently satisfied that she was not being

exposed, and with friends about her able to assure her that the operation was performed in such a manner. All such operations I have been able to perform in this way without pain, and many of them are as severe tests as could be required of the *analgesic* effect of rapid breathing.

It has been universally recognized that the relaxation of the sphincters is one of the best evidences of *anæsthesia*, and experienced surgeons early taught that it required more thorough etherization for operations in these parts than in others on account of their hyperæsthetic condition. Any one who has attempted the rapid dilatation of the urethra—the recently proposed cure for irritability there in females suffering with many forms of womb trouble, which Professor Charles D. Meigs used to describe as a pure *sphincterismus*—can sustain that view. On one day, in February last, I performed this operation most successfully in three different cases, the patients living ten miles apart. In two of them I tested the rapid breathing, and in the other I used no means whatever, on account of disinclination on the part of the patient, to prevent the pain. The former have no recollections of having gone through a severe operation, and have frequently expressed themselves as being most willing to undergo the procedure again should it be required, whereas the last declares that nothing could ever induce her to submit to such pain again, although the operation gave her the desired relief.

Amongst my operations for fistula in ano, under this means, I had one case which had been operated on once before by the bistoury, and without any anæsthetic. This patient actually laughed when I told him the operation was done, and at first he was disposed not to believe me. In his case I used the old-fashioned instrument for the purpose, a *Syringotome*, one that has been used for this purpose by my ancestors for over a hundred years. It is nothing but a steel, sickle-shaped blade, a quadrant of a circle of two and a half inches radius, with a long and very flexible, silver probe-end. It renders the operation a very simple and quickly performed one. My operation was not through the track of the former fistula—it had been well cured—but for one on the other side of the anal orifice, and which seemed like a very much less serious affair than the first evidently had been. All these circumstances are worthy of being noted in a report of this man's comparison of the two operations. In my operation he had no pain; in the other, he said, he had had a great deal.

I could prolong this paper, already sufficiently long for the character of such communications, by entering into details of a variety of cases other than those to which I have alluded; but I have certainly given enough of facts to induce others to give the method a fair trial, and if I shall have succeeded so far, I shall be perfectly satisfied; my purpose has been to earnestly fix the attention of the profession to this subject, with the conviction on my own part that the plan will prove a *desideratum*, even with the many means of anæsthesia which we possess.[1] It is to be earnestly hoped that none will show themselves too ready to condemn or

[1] Here I would again most distinctly repudiate all idea or purpose of even proposing to substitute this for ether or chloroform in major operations (save those about the mouth). I have used it in some such where it was not convenient or expedient to use either of those means, or where, I will confess, it was my object to test this in a severe manner; and the results, as I have mentioned, have been satisfactory, but not such as to demand its use in the place of those means which can produce a more thorough insensibility or complete anæsthesia than I have claimed for this.

ignore this process, as was the case in the early history of ether and chloroform, from failures in the first attempts, much less from the inability, as some say, to see any philosophy in it, or, as some have expressed themselves, from its being too simple a measure not to have been discovered and used with satisfaction before this late date if there had been any merit in it. We have seen the full value of such objections in our retrospect of the history of nitrous oxide and of ether, and surely no one at the present day is going to suffer himself to be misguided by want of zeal or by excessive conservatism in his profession. To prevent the occurrence of these, I will now give minutiæ, as far as my experience will allow me, as to the way of bringing about this insensibility to pain, and also what facts I possess towards the modus operandi of the process, or showing any rationale for it.

In operations about the air-passages, I may also say about the face and scalp, as well as about the ear, and even about the eye and its appendages, the sitting posture is the one to be preferred. This, however, is not, according to my experience, the most advantageous one for the induction of the analgesic state by this method. In all instances where I can, I now adopt the recumbent posture on one side, as in such a position the desired state is I find more promptly induced. To prevent the diversion of the patient's mind from his part in the matter, it is frequently beneficial to cover the face by a handkerchief: this may, in some instances, prove disadvantageous, from the idea the patient may take up that he is really to be etherized; in other instances, it may be in that way of service.

Following strictly Dr. Bonwill's directions, I always at first told my patients "to breathe as deeply and as rapidly" as they could;[1] but studying out their cases I was led to see that the rapidity of breathing was the most essential part, and that its rate of frequency was unavoidably at the expense of depth; a deep or full breath of course requires much longer time than one of an opposite character, and it is also essentially an inspiration; whereas a rapid breath partakes more and more, as it is increased in frequency, of the characters of *expiration*. This is not to be wondered at; it is clearly due to the difference of circumstances of the two movements. All the circumstances concerned in respiration favor the act of expiration. Both the elasticity of the lungs themselves, and that of the walls of the thoracic cavity, aid the expiratory movement, whilst they offer a corresponding resistance to the inspiratory; and, besides these, we have also to take into consideration the atmospheric pressure over the surface of the chest which is not only favorable to expiration, but which increases the resistance to inspiration as the depth of the latter is made greater, and, according to Dr. Hutchinson's researches,[2] this is in an arithmetical progression. These conditions, it would seem from Dr. Carpenter's calculations,[3] require a muscular power in an adult man to overcome them in an inspiration made to its full length equivalent to "not less than 1000 lbs." All which is correspondingly favorable to an expiration begun at the end of such an inspiration.

Even where my patients were progressing well in their efforts, and I urged them "to breathe deeper and faster," the effort for depth would

[1] See Dr. Bradford's report of my Clinical Lecture, in Philadelphia Medical Times, March 4, 1876.

[2] Cyclopædia of Anatomy and Physiology, art. Thorax, p. 1056.

[3] See his Physiology, p. 512.

always produce an interruption of rhythm of the velocity, and I then got to urging them "to breathe faster and deeper;" then "to breathe as fast" as they could; and, finally, notwithstanding I had had the importance of the *depth* of the breathing impressed on my mind, I recurred to my experiences with ether, chloroform, and other vapor, of the advantage of urging the patient to blow out, and adopted with great satisfaction here the plan of making my patients to expire as fast as they could. The fact of the very circumstances of a deep inspiration making an increase in the power to expire, became then very evident; the patient would always, after blowing as fast as he could several times, be compelled to take a deep inspiration; here we demonstrated the French "*besoin de respirer*," against which the patient would show his inability to exert any excess of counteraction, and found a satisfactory proof that no effort of the patient's will could carry the process to a point of serious suspension of respiration. These advantages of expiration over inspiration also come into play when we try to have efforts made to exaggerate either for any length of time, especially if the patient has become stupefied by such; he then requires to be constantly urged to go on with the *breathing in* as fast as possible, whereas, once started to blowing out rapidly, he will continue the blowing when he becomes stupefied, although not with the same earnestness, yet with the same rapidity. From recent conversations with Dr. Bonwill, I find that he has been led to adopt the same directions to his patients.

This altering, by an effort of the will on the part of a patient, the frequency and character of the respiration in the manner described, has an effect of course on the frequency of the heart's action, but this is, I may say, not directly related to the frequency of breathing, but corresponds rather with the exertion made by the patient. The force of the pulse does, however, here, as with ether, chloroform, etc., furnish evidence of the impression being made on the nervous system, never, however, to an extent like that of either of those agents, and to a decided extent only when the utmost impression to be made has been effected. This change is one of *diminution* in the force of the heart, and is essentially like that of a natural sleep, but is as much more marked than the latter as that by chloroform is over that by ether. It never can become excessive for the reasons we have given. Bourdon long since[1] declared that no one can by any exercise of the will over the breath destroy the heart's action. One can therefore continue, without any fear or hesitation, to urge the patient to keep up this breathing process. It generally requires from three to five minutes of constant urging to breathe in this manner, at a rate of from forty to fifty or more inspirations in a minute, to bring about the desired condition.

What will strike everybody, I am sure, as remarkable, anticipating the influence of dread, is, that females always require less time for the purpose than males, no matter what may be their age relatively. Those of middle life always require more time than either the young or aged. The very young, those under ten years, are the most difficult to manage, chiefly, I think, through their fear; more time is also, I have always noticed, required in a cold clear atmosphere, than in an opposite one. The same class of patients, as a rule, takes five minutes in a cool room of a winter's day to induce the same state of analgesia which would need only three of a close summer's day. All these facts had been care-

[1] Recherches sur la Méchanisme de la Respiration.

fully observed by myself before I had given the *rationale* of the process any serious thought or consideration.

The first effect of this breathing, appreciable to an observer, is a change in the color of the face; the lips, the cheeks, and the tint of the face, at first brightened, generally become pallid, then leaden or bluish; and with these latter changes the expression is altered and wanting in animation. If the eyes are open, they have a vacant look, and their lids begin to droop; the patient assumes the look of one much overcome by fatigue, and then of one on the verge of an ordinary sleep. Then often ensues, especially in an hysterical young girl, a state of very positive muscular rigidity; before this however ensues, the state of analgesia has been brought about, and is indicated by want of recognition of the prickings of pins or the like, for the patient will always feel the abrupt contact of obtuse bodies—even the touch of your hand—but will not now experience any pain even from a bistoury or scalpel. The state of rigidity, which I have just referred to, resembles much that of catalepsy, and what is frequently noticeable in cases where anæsthetics are being administered. The power to move is embarrassed by this; the will, however, would seem to have persisted, as the patients tell you afterwards, and may even show you during this state, by their efforts without full ability to follow your directions in moving or suffering you to move a limb. This rigidity of the muscular system is by no means of constant occurrence, is often very slight and transient, and gives way. It is clearly from the semi-asphyxiated state induced by the patient's breathing, for on ceasing to urge on him the rapid rate, he relapses into a quiet, normal rate, and so, soon allowing his blood to recover from its intensely purple hue, he comes out of this state, and gradually recovers his ability to appreciate and remember the contact of foreign bodies and to move away from them.

The subjective phenomena of this process are, as far as they go, essentially like those from nitrous oxide, ether, and even chloroform. There is, first, the swimming or confusion in the head, and the loss of perfect or acute consciousness, attended with a sensation of tingling and distension of the surface—this latter beginning at the sentient extremities, and the hands especially, and passing upwards, and closely following these sensations comes the condition of analgesia, absence of appreciation of painful impressions on those sentient nerves. It is, as I have before remarked, to be particularly noticed that there is in this state the want of appreciation of ordinarily painful impressions, and in this respect we see the resemblance most marked to nitrous oxide; it will be remembered that it was this effect of the laughing gas which attracted the attention of Wells, and he showed that the analgesia may be there most perfect, without the concurrence of the state of anæsthesia, although the distinction between the two states was not then known. These same subjective phenomena, as I have intimated, occur in the administration of ether and chloroform; but they occur then in such rapid succession, and are so soon followed by a profounder impression on the cerebral centre, that there are no recollections of them afterwards, and this was more generally the case in the early history of the use of anæsthetics than it is now, from the fact that there is not the care taken now to secure a free dilution of the vapor by atmospheric air that there was then; the anæsthetic state is now hastened on as rapidly as possible by the mode of administering the vapor, by giving it as undiluted as possible. In the administration of nitrous oxide, as originally proposed by Sir H. Davy,

the air expired into the bag at the close of each breath is charged with carbonic acid and carbonic oxide gases, and, as the nitrous oxide becomes exhausted from the bag, these same gases are breathed in and breathed over, again and again; and how much, it may be asked, does the insensibility from this administration depend upon these very gases of expired air? Who indeed, on careful consideration of the prodromes of *all* anæsthetics, will not be disposed to attribute those very prodromes to the same physiological conditions? All modern anæsthetics, so called, owe their property to their mode of impressing the nervous system, and that essentially through the respiratory organs, intoxicating the blood, and this acting secondarily through the circulating organs by which it is conveyed to the nerve centres. The prodromes in all of them are most marvellously alike in their individual features as well as in their order of succession.

Ether and chloroform are hydro-carbons, so called, and their vapors not only furnish those elements proportional to the specific gravity of said vapors, but so relatively cut off the supply of oxygen by which those same elements, hydrogen and carbon, already in, are to be elaborated from, the venous blood of the lungs. Before they even impregnate the blood of the lungs, they thus arrest or interfere with its means of purification, and this they do clearly by cutting off the oxygen of atmospheric air, for the moment you let that air in a state of purity take their place, you have that elaboration resumed, and, more than that, you have all the abnormal impressions on the brain made to disappear. Let the patient, however, breathe an impure air, one charged with so-called carbonic acid gas, for instance, and the difficulty of breathing continues, and with it all the phenomena now recognized as belonging to the asphyxiated state show themselves in regular succession, proportionate, however, as Felix Leblanc has shown, more especially to the quantity of carbonic oxide so thrown into the circulating fluid of the brain and spinal marrow from the lungs by way of the heart, thus affecting essentially the blood corpuscles and making them inert; nay more, they are then no longer, as Bernard has shown, carriers or capable of being carriers of oxygen, the great vivifying as well as purifying element of the fresh air.

In 1854, Mons. Chenot[1] gave a chemical explanation of this action of the oxide of carbon on the system. He there admits two consequences of the action of the gas; he says when it penetrates the blood by the lungs, it takes the oxygen of the blood and passes into carbonic acid gas; and secondly it produces an exaltation of temperature which results in a sort of inflammation of all the organs and tissues. But M. Chenot, as Bernard remarks, is a metallurgist, and his theory is purely a chemical one. Bernard had, prior to the date of Chenot's communication, in fact as early as 1842, observed that animals, asphyxiated by the oxide of carbon, had their *venous* blood made red like arterial blood, and Troja had observed this same thing before Bernard. The last-named authority, Claude Bernard, and we have no better on the subject, insists upon this change of color of the blood, the peculiar reddening of the blood corpuscles, and a reduction of the temperature, as pathognomonic effects of carbonic oxide, as contrasted with those of carbonic acid intoxication of the blood, where on the contrary the color of the blood is blue, and the temperature increased. The hæmoglobin which constitutes the

[1] Chenot, Note sur l'Oxide de Carbon, Comptes Rendus de l'Académie des Sciences, t. xxxviii. p. 735 et seq.

coloring substance of the blood corpuscles, plays in them a purely chemical part, and we are no longer allowed to believe that the corpuscles act mechanically, dissolving the oxygen; on the contrary, we have the best proof that this substance (hæmoglobin) forms a true combination with the oxygen. Furthermore we now know that this substance will combine likewise with other gases. The distinguished German physiological chemist, Hoppe-Seyler, has studied such crystalline combinations of it with carbonic oxide, nitrous oxide, bromide of nitrogen, the vapors of ether, chloroform, and the like, as well as those with oyxgen; and has shown that they can all displace the oxygen in its combination. When we have ether used, it has been proved to act in this way likewise, and as promptly whether the hæmoglobin has been previously in combination with oxygen, carbonic acid, or carbonic oxide gases. The combination of hæmoglobin with oxygen is less stable than that with carbonic oxide, and the latter less so than that with bromide of nitrogen.

The phenomena attending these combinations in *arterial* blood, at the expense of its oxygen, are, Bernard remarks,[1] attended by symptoms constant in their character, and the first with them all is loss of sensibility; this is so marked where carbonic oxide is the combining agent, that Gabriel Tourdes,[2] of Strasbourg, has compared its action to that of chloroform and proposed it as an anæsthetic agent. Speaking of this proposal of Mons. Tourdes, Bernard says "it is true that carbonic oxide can be an anæsthetic, but in this way carbonic acid can also be one. But the word anæsthetic, thus generalized, could be applied to a crowd of different articles." "Indeed," he adds, "hemorrhage is thus an anæsthetic, since its first effect is to destroy sensibility. But I believe," he further says, "we ought to reserve the name for substances which produce anæsthesia without causing any great danger to existence."[3] In his study of asphyxia from the fumes of charcoal, this same eminent experimentalist (Bernard), besides pointing out the phenomena characterizing the action of carbonic oxide and carbonic acid, has shown that the latter is not destruction of the blood corpuscles as the former is, that it is displaced in them by oxygen, and that the last-named gas converts the lymph or white corpuscles into red corpuscles, in the lungs, by this very action with hæmoglobin to which we have been referring. By means of the spectroscope, Bernard has been able to follow the action of carbonic oxide in all its stages, and has shown that it is only when the blood seems completely imbued by this gas that death takes place, and that, when it is gradually introduced, it produces an anæmic state by this destruction of the corpuscles being more rapid than their removal by the oxygen of the air through the lungs. Death occurs from the damage done directly to the heart. Death from carbonic acid can ensue only when the supply of oxygen has been entirely cut off.

With such facts before us, we can have no difficulty in recognizing that all agents which produce insensibility to pain, when applied through the lungs, act essentially as before declared in the same way; and though complete anæsthesia is not a state of asphyxia, we can see how the two states may occur together; how the latter, occurring in attempts to induce the former, may bring about a fatal result; and how the former, carried to an extreme point of saturation, may in itself cause death. We

[1] Cinquième Leçon.

[3] Op. cit. p. 420.

have also no difficulty in comprehending how the state of analgesia always occurs from *all* these agents *prior* to any interference by them with reflex actions.

There is therefore no impropriety in turning our attention to the mode in which rapid breathing can bring about this state of analgesia, although the process is an extreme novelty. From what I have related as to my own experiences of the facilities for inducing this state, it would seem that it is not a condition produced by increasing the essential respiratory function, viz., that of introducing oxygen into the blood and taking carbonic acid from it. The position in which I have found the patient most readily to be affected, that of reclining and resting on one side of the chest, and the best manner for him to breathe, that by exaggerating his efforts at *expiration*, are against such an idea. These rather imitate the conditions consequent on a pleurisy or pneumonia, where we have a diminution of the oxidation and of the decarbonization of the blood, and where we have, to sustain this analogy, not only a diminution in the depth of the inspirations, but an abnormal increase in their relative frequency over that of the pulse, as likewise the peculiar buccal expiration, so marked in them, and which the patient readily lapses into when we urge him on in his rapid breathing. Starting out to blow fast, each inspiration gets less and less in depth, and the patient while increasing by his will that part of the action called supracostal, and which is so characteristic of woman's breathing, involuntarily diminishes that of the lower part of the chest. The greater familiarity of females with the essentials of this mode of breathing no doubt, in part at least, will explain their greater facility in being inducted into the state of analgesia by the process.

We have also as evidence against any increase properly of the respiratory function occurring, that the blood is positively cyanosed. This is not only readily appreciated in the patient's hue of surface, but can always, according to my experience, be detected in the venous hue of the blood which may escape in operations under this state, and also in that of a new-born child when the process has been used in the birth. In all instances where I have been able to test the point, I have likewise detected a positive reduction of temperature occurring in patients whilst in this analgesic state.

Again, we have the most definite proof that increase of frequency of respiration positively diminishes the amount of carbonic acid thrown out. Thus Vierodt[1] found that, if he respired only six times in a minute, the quantity of carbonic acid was 5.5 per cent. of the whole air exhaled; with twelve respirations, it was 4.2; with twenty-four, it was 3.2; with forty-eight, it was 3.0, and with ninety-six, it was 2.6 per cent.[2] According to experiments of Letellier, quoted by Kirkes,[3] about 100 per cent. more of carbonic acid is exhaled by warm-blooded animals at 0° than at 104° Fahr., and, if we take the mean results of Crawford and Lavoisier, it may be found by an easy calculation that 20 per cent. more of oxygen is consumed at 50° than at 82° Fahr. Such facts as these tend very clearly to explain the difference I have noticed, as stated before, in *temperature* and *humidity* as favoring the induction of this state on the idea that it is rather from a *diminution* in the respiratory function, a cut-

[1] Physiologie des Athmens, p. 102.

[3] Physiology, p. 135.

ting off of the normal supply of *oxygen* and retaining the *carbonic acid* in the blood to be sent to the nerve centres.

The variations which have been noted by numerous observers in the exhalation of carbonic acid by the lungs as produced by age, sex, development of body, states of repose, sleep, and watchfulness, likewise correspond with the effects of those considerations whenever I have noted them in my cases.

Every circumstance would therefore seem to indicate that this process of inducing insensibility to pain is one essentially of diminished oxidation and decarbonization of the blood, and recognizing such a state as belonging to the initiation stage of all anæsthetics, when *insensibility to pain* is positively marked, we have no necessity for begging any special theory for this process, as in its action it readily comes under the category of such agents, and is thus not either an *absurdity* or an *impossibility* from a scientific point of view.

OBSERVATIONS ON THE TEMPERATURE OF OSTEOSARCOMA.

BY

PROF. J. A. ESTLANDER,

OF HELSINGFORS, FINLAND.

Among the many different species in the great group of diseases called tumors, the sarcoma has always attracted special attention. During the time that it was considered a form of cancer, it differed from the other forms of this disease by its appearance in younger persons, and, since it has received its present name, it has continued to make itself conspicuous by its not very rare occurrence, the rapidity of its growth, and particularly by the most awful speed with which it often destroys the organism. Its history is therefore comparatively well elaborated, but, in the systems of surgery which I have had occasion to consult, I have not found any attention paid to one of its symptoms which seems to me to be very constant, and to offer a considerable interest on account of its being intimately connected with the nature of the growth ; I refer to the high temperature which it shows when it has attained a certain size, and is rapidly increasing. The following accounts of some cases will furnish a more complete description of this symptom.

Case I.—Matilda Holm, a workingman's wife, 28 years old, had always enjoyed good health until towards the end of her last pregnancy, when she began to feel pain in her right hip when walking. Three months previous to her admission she was confined, and afterwards this pain became very severe, and, three weeks prior to her entering the hospital, she began to feel a continuous and intense aching which she sometimes felt down to the knee and foot. At the same time she also observed a swelling around the crista ilii, and was troubled with a sensation alternately of heat and cold in the body. In other respects her state of health was normal. When the pain by degrees increased more and more, she sought and obtained admittance at the Surgical Clinique on Feb. 20, 1873.

At the time of her admission, her condition was as follows : Body well built, strong, and not lean ; the internal organs normal. Around the whole crista ilii on the right side, as well towards the inside of the belly as outwardly, a large immobile tumor with lobulated surface, solid consistency, but indistinct limits. The skin over the tumor was free, movable, and not tight, but traversed by large subcutaneous veins. The tumor itself, but not the surrounding parts, very tender to the touch. Crista ilii, not only the parts covered by the tumor, but also the parts adjacent to it, easily permeable to the acupuncture needle. A thermometer placed on the tumor and covered with cotton shows 37.8° centigrade, while the same instrument on the corresponding place of the left side, and on the inner side of the thigh, shows only 36.8°, and in the axilla 37.2°, a result which reiterated measurings on the following days showed to be constant.

As there could naturally be no question of any operation, the treatment was only symptomatic. The tumor increased rapidly, and the patient's strength sank in the same proportion. On May 11, the right leg and foot began to get œdematous, and shortly afterwards also the other. May 24, a severe diar-

rhœa appeared, and the patient died on the 28th of the same month. On post-mortem examination, the sarcoma was found to extend backwards to the os sacrum, and downwards to a little below Poupart's ligament. Half of the ilium was destroyed, and the rest rarefied and friable; metastatic nodules were found in the lungs and kidneys. The microscope showed the growth to be a round-celled sarcoma.

Case II.—Erland Engström, a farmer's son, 19 years old, had two years before, noticed a small knob, hard as bone, on the right tibia somewhere about the middle. In the succeeding spring it was as large as a hen's egg, and the following Christmas as large as a man's fist, but after that time it began to grow more rapidly, and moreover began to be painful. The movements of the leg were not much impaired, for on May 11, 1875, the day he was received at the Surgical Clinique, he had walked a distance of nearly seven English miles.

On his admission, the following was his condition: The patient, otherwise in complete health, had on his right leg a tumor with lobulated surface, and a consistency at some places more soft, at others more solid. The tumor extended from within an inch below the patella, close to the ankle-joint, and occupied nearly the whole circumference of the leg, in such a way that it was most developed in front, and behind had pressed the muscles from the bone to which it was solidly attached. From above downwards it measured twenty-five centimetres, from before backwards eighteen, and the circumference was seventy-five. The skin was very highly distended, but everywhere free and movable. The mobility in the ankle-joint considerably diminished, the foot œdematous, the inguinal glands on this side slightly swollen. A thermometer placed on the tumor showed 37.2° centigrade, but on the corresponding part of the left leg, or on the thigh, only 36°. Reiterated observations on the following days gave nearly the same results.

On May 21, I amputated the thigh, and the patient left the hospital on August 16, with the swelling of the inguinal glands considerably diminished.

The tumor consisted of a compound mixture of osteoma, enchondroma, and sarcoma, with here and there some small cysts. These three tissues were generally so distributed that the first was in connection with and close to the bone, the third more on the surface, and the second, which showed an exquisite areolar structure, seemed to follow no rule, and had probably in the beginning formed the whole substance of the tumor. The muscles of the leg, in form of highly distended thick fasciæ, covered the surface of the growth.

Case III.—Johan Kujola, a farmer's son, 32 years old, had noticed about two years before that his right knee began to swell and get stiff, and, as during the last months this swelling had rapidly increased, he applied and was admitted to the Surgical Clinique on Feb. 22, 1876.

The patient's condition at that time was as follows: His constitution was rather weak, but all the internal organs were healthy. Over the right knee-joint, on the anterior and inner side, was a tumor closely connected with the bone, as large as a child's head, and with no well-defined limits. In front it had a lobulated surface, but on the inner side was covered with a lamella of bone so thin that it broke into two pieces, on the first examination. The tumor was pulsating, but the circumference of the bone, together with the tumor, could neither by manual compression nor by Esmarch's bandage be reduced more than about one centimetre. The movements of the knee, although somewhat restricted, were not accompanied with any pain, and there was no collection of fluid in the joint. The glands beneath Poupart's ligament were somewhat swollen. The thermometer on the same day showed 39° centigrade in the axilla, 38.3° on the tumor, and 37° on the corresponding part of the other thigh; and the next day, in the axilla 38°, on the tumor 38°, and on the corresponding part of the other thigh 36.5°.

As there could be no doubt of the diagnosis of strongly vascularized osteosarcoma, and as the swollen glands could easily have been extirpated, I pro-

posed amputation of the thigh, but the patient refused to submit to the operation, and left the hospital on March 3.

Case IV.—Fredrika Petterson, a sailor's widow, 60 years old, had seven or eight years before noticed, on the front side of the right leg, a small knob which was immovably fixed to the bones. As she felt no inconvenience, she paid no attention to this growth until last September, when it began to pain her. She then went to a physician, who found the tumor as large as a small apple, with a scarcely perceptible swelling of the inguinal glands. On Feb. 10, of this year, she came to the Surgical Polyclinique, and as I found the size of the tumor as last mentioned, but the glands considerably more swollen, I proposed to extirpate both. The patient did not consent, but when the tumor shortly afterwards increased with great rapidity, the skin ulcerated, and the pains became much worse, she returned and was admitted to the hospital on May 11, 1876.

On her entrance, she presented a tumor firmly attached to the front part of the right tibia, as large as a child's head; its consistence was soft, and at certain points nearly fluctuating. The skin over the base of the tumor was tightly stretched, and had on the top begun to ulcerate. Beneath Poupart's ligament there was a solid tumour as large as an egg, and, around, several lymphatic glands considerably swollen. The thermometer on the tumor constantly showed 38.1°; on the corresponding part of the other leg 37°; and in the axilla 37.1° centigrade.

As I supposed that the tibia was so much involved that an extirpation was no longer advisable, on the 15th of the same month I performed Gritti's exarticulation at the knee-joint, and, besides, extirpation of the inguinal glands; and when I left home, on August 14, the patient was ready to leave the hospital. By examination of the tumor I found it to be a spindle-celled sarcoma which had destroyed the front part of the bone and entered into the medullary canal. Between the skin and the glands there was no trace of suppuration.

Case V.—Anders Mäkiavütala, farmer, thirty-nine years old, had when a child of two years been burnt by hot water on the right side of the front part of the chest. At the age of twenty and some years, the cicatrix began to grow out in the form of a red knob, which increased so slowly that by last autumn it had only attained the size of a walnut. From that time onward it had begun to grow more rapidly, and, after the top of it had sloughed off, the patient had repeatedly had bleedings from it.

On his admission, on June 21, 1876, the state of the patient was as follows: He was strongly built and well fed. The entire right pectoral region was occupied by a cylindric tumor, nine and a half centimetres high; its sides were covered with a distended, red, and thin skin, and its top formed an ulcer thirteen centimetres in diameter. The tumor was movable and not connected with the pectoral muscle, and felt at some points very soft, at others more solid. No swollen glands were to be found either in the axilla or the supraclavicular region. A thermometer on the ulceration at the top of the tumor showed 38.8° centigrade; on the corresponding part of the left side of the chest, 38°; and in the axilla, 38.7°. After extirpation, on June 23, the tumor was found to be a round-celled sarcoma. By means of skin-grafting the wound was nearly healed when I left home on August 14.

The temperature was measured in the following manner: The quicksilver bulb of the thermometer was fastened to the skin with strips of sticking-plaster, and afterwards the instrument and the whole part of the body covered with a thick layer of cotton. This manner of measuring could not, of course, pretend to be very exact, if the question were to ascertain the absolute temperature of any part of the body, but as the sole question here is about the difference between two parts measured by the same instrument and in the same manner, the result ought to be very nearly true. The above related records show, then, that the temperature

of a rapidly-increasing sarcoma is commonly one and often one and a half degrees of Celsius's scale, higher than that of the corresponding region on the other side of the body.

The high temperature in the tumor might, perhaps, be supposed to be a symptom of inflammation in the distended skin, but Case V., where the skin to a large extent had ulcerated away and the thermometer was placed on this spot, showed that it depended on the tumor itself, and in the other cases, if there had been any inflammation in the skin, there ought to have been perceived, somewhere under it, an abscess; which, however, was not the case with any of the patients, although special attention was paid to this point.

The above-described cases show that all the tumors were rapidly increasing, and, as it may generally be considered a rule that a tumor contains in the same proportion the more arterial blood the more rapidly it grows, it might, therefore, be supposed that the high temperature in these cases depended only on their rich supply of blood, particularly since the case of pulsating tumor presented the highest temperature among them. Without wishing to deny the importance of the arterial blood in this respect, I think we can, perhaps, show the probable presence of yet another source of this temperature. When we consider that even the best thermometers always show the temperature several tenths of a degree lower than it really is, and when we add this difference to the resulting temperature found with the tumors, we get as result a sum considerably higher than the temperature of the arterial blood. This authorizes the conclusion that this surplus is produced in the tumor itself, and that thus the high temperature of a sarcoma is the effect not only of its richness in bloodvessels, but likewise of the active processes going on in the elements of its tissues. It may be that this demonstration, as supported only by a few observations, has not much more value than a common hypothesis; but at all events it explains the relation between the rapid growth of the tumor and its high temperature more completely than the presence of a great quantity of arterial blood does. A teleangiectasis contains relatively more arterial blood than any other tumor, and nevertheless it sometimes disappears by itself.

If we, following the most recent opinions, consider the fungus hæmatodes in Case III. (which was not operated upon) as a sarcoma and not as a cancer, then all the narrated cases have that feature in common that they were all sarcomatous growths, for even the tumor in Case II. contained this form of growth, although the greater part consisted of cartilaginous and osseous tissue. But naturally this is not yet a proof that only the round, or spindle, or giant-cells possess this peculiarity, for the second of the reported cases seemingly leads to hint that on the contrary even the cartilaginous tissue has the same; and it seems probable that it belongs to every tumor whose elements are capable of a rapid increase in number and development.

Of all the different parts of surgery which, during the last decade, have been the object of scientific investigations, perhaps none has been so greatly developed and changed as that which deals with tumors. For at times previous it consisted only of a confusion of special observations, but now it is a well-arranged field where every growth, no matter how varying its form may be, has its given place. But this change for the better mostly regards their patho-anatomical structure, for their clinical history is pretty nearly the same as before. I hope, therefore, that this small contribution in the latter respect will not be entirely wanting in interest.

ON STONE IN THE BLADDER IN FINLAND.

BY

PROF. J. A. ESTLANDER,

OF HELSINGFORS, FINLAND.

To facilitate the explanation of the peculiar conditions, with respect to stone in the bladder, which exist in my native country, Finland, I will divide all cases of this disease with respect to their etiology into two groups. The first where there is no disease in the urinary organs and the stone seems to be of constitutional origin, and the second where the calculus clearly depends on a local disorder. When cases of stone belonging to the first group frequently occur in one country, and are, on the other hand, very rare or altogether wanting in another country, then the endemic causes are clearly perceptible. But when the calculus originates in diseases of the kidneys or in the many causes which prevent the bladder from completely emptying its contents—as for instance paresis of the muscles of the bladder, or obstruction of any kind in the urethra, etc.—then the question arises, in what relation do these cases stand to the general endemic causes? Are they absolutely independent of them or not? For my part I am inclined to answer this question to a certain extent in the negative. It is true that the rich or so-called upper classes of the different countries all over the world live pretty nearly in the same manner, and are precisely by their manner of living on one side more exposed to calculus, and on the other side more independent of the endemic causes of the disorder, than the lower classes. But still, as the influence of climate, water, temperature, etc., is never completely to be avoided, the rich must, at least to a certain degree, be subject to the same epidemic laws as the other classes of the population. If I then suppose a country where no endemic causes of stone in the bladder exist, there we should, as a general rule, entirely miss all the cases of constitutional origin, and find the cases of local origin principally amongst the upper classes, and that less frequently than elsewhere. This is just the case with Finland.

Some statistical figures, collected from the Case Book of the Surgical Clinique, at the University of Finland, for the last forty-four years, will show the truth of this in respect to the first group of calculous cases. During this time of nearly half a century, only one case has presented itself, that being in a farmer of forty-one years, whom, in 1863, I operated upon for a phosphatic stone in the bladder. This isolated fact is the more remarkable, as several such operations have been performed in the Clinique, but the patients always belonged to the Russian nation, particularly from the province of Jaroslaw. As Finland, with a population, on December 31, 1875, of 1,829,919, has a surface of not less than 6783 Swedish square miles (Lapland included), and the means of communication between the different parts of the country have to within the last ten years remained undeveloped, it might be supposed that cases of this disease had occurred in any of the eight provinces into which the Grand Duchy is divided, without presenting themselves at the Surgical Clinique

of the University, although it is the only special hospital in the country. In order to gain a decided conviction that this circumstance had no determining influence, I communicated by letter with the doctors superintending the hospitals erected by the government in each of those provinces, and they each and all returned the same answer: that in the last ten or fifteen years during which they had been at the hospitals, they had never met with a case of stone in the bladder.

Cases belonging to the second group of calculus have been exceedingly rare amongst that part of the population which frequents the hospitals, and have been principally limited to stones depending on paralysis of the bladder. Not one single case of renal calculus is recorded in the Case Book. But in my private practice I have had occasion to treat a great many patients of that kind; all from the richer classes. Among cases of vesical calculus, most of them depending on hypertrophy of the prostate, about twelve may have occurred among my countrymen. I have no precise data to judge of the frequency of stone in the upper classes, but it seems to me that this number is remarkably small to correspond with a practice of seventeen years, during which time I have been the only *ex-professo* surgeon in the country.

From the facts I have just now stated, I think I am justified in concluding that stone in the bladder occurs in Finland almost exclusively among the upper classes, and originates most frequently in disorders of the urinary organs. It seems as if the causes of so pronounced an immunity for a whole country ought to be easily discovered, but such is not the case. Here just as well as anywhere, where we have to do with the etiology of diseases, the facts we observe are the result of many co-operating circumstances. As it would be out of time and place here to enter into any long discussion of the different influences which c uld possibly be considered as contributing to this immunity, I will only point out the circumstances which seem to me to merit special attention in this respect. The quality of the water is generally considered very important, and to this matter we ought to assign the first place. The land consists principally of granite mountains (ground even during the glacial period), vast sandhills, and barren heaths, which the vegetation of many thousand years has covered with a scanty crust of earth. The water of springs, rivers, and lakes, therefore, contains only a very small quantity of alkaline salts. As an instance I will quote an analysis made by Prof. J. Chydenius of the water in the Wanda River, which supplies the waterworks of Helsingfors.

100,000 grammes contained 7 grammes of solid substance, whereof—

Chloride of sodium	0.63 grammes.
Carbonate of lime	1.88 "
Carbonate of magnesia	0.81 "
Silicic acid	0.48 "
Organic humus-like substance	2.55 "

Thus the purity of the water is very remarkable, and, as water forms the principal part of the nourishment of a people, we certainly must consider this quality as the main cause of immunity. Another cause might be found in the food of the Finnish people, which generally consists of cereals, fish, potatoes, and milk (nearly always sour), and very seldom meat; in fact I do not think any other people consumes so much lactic acid and so little meat. It would not perhaps be difficult to find out at least the relation between meat as food and the uric acid which forms the greater part of the calculi of constitutional origin, but I content

myself with simply pointing out the most striking features of the Finnish people's manner of living, hoping that a comparison with that of other peoples enjoying the same immunity will, better than any hypothesis, show whether those characteristic points exercise any influence in that respect or not. There would yet remain some circumstances worthy of notice, as for instance the habit of taking once a week a bath in a room filled with hot steam—a habit which is as old as the people itself, and so common that the poorest man never neglects it—but that I think I have already too long claimed your attention for this subject.

SECTION ON DERMATOLOGY AND SYPHILOGRAPHY.

VARIATIONS IN TYPE AND IN PREVALENCE OF DISEASES OF THE SKIN IN DIFFERENT COUNTRIES OF EQUAL CIVILIZATION.

BY
JAMES C. WHITE, M.D.,
PROFESSOR OF DERMATOLOGY IN HARVARD UNIVERSITY.

It has long been well known that some diseases of the skin are more or less strictly confined to certain distinct geographical or anthropological districts, and that others assume marked variations of type in different countries. The number of such affections, however, is small. The impression has been gradually taking form, of late, that similar variations in type and prevalence exist much more generally among skin diseases than has been hitherto recognized, nor is it strange that such a fact, if fact it be, should have remained so long undetermined. The slow growth of dermatology prior to the last quarter of a century; the babel-like confusion in nomenclature which still hampers its various schools and writers; and the lack of competent observers, except in a few of the principal centres of the most civilized populations, have prevented the collection and comparison of the necessary data from all parts of the world, upon which the establishment of such facts must rest. It is not my intention to consider this subject now under as broad a scope as the title of this paper would suggest, but rather to present my views and the facts which I have been able to gather relating to the differences between these affections, as they occur here at home and in the countries which afford means of comparative observation. In this narrower compass we may, perhaps, wisely essay the first step towards the complete solution of the question.

As just stated, this question of variation has only slowly forced itself upon the perception of dermatologists. Owing to the entire absence in America of any regular instruction in dermatology in our medical

schools, and of opportunity of clinical observation of skin diseases in our hospitals and dispensaries, until within the last few years, those of us here who have labored to supply such deficiencies, and have devoted ourselves specially or exclusively to the study of dermatology, got our first systematic and practical conceptions of skin diseases in the schools of Europe; conceptions no doubt often tinged over-strongly in this or that direction by the individual opinions and theories of some eminent teacher, and which we have slowly more or less modified since then by more extended and broader personal observation; still it was in foreign schools that we first familiarized ourselves with the types of cutaneous disease, and the impressions there gained we have retained as permanent standards for comparison with the results of our later and more practical experience at home. Gradually, perhaps too slowly in the case of those of us whose reverence for a master's precepts has been strongly inherent, we have become aware of differences of various kinds in some of the diseases here and the same affections as seen abroad, differences in course, in severity, in prevalence, in behavior under treatment, etc. These later impressions have been almost wholly the growth of individual observation, and with the exception of a limited mutual interchange of opinion on the subject in conversation or correspondence, and brief allusion to some of the more noticeable variations in occasional papers, the question of such differences has not been presented or discussed in a general way by any of our dermatologists. Nor is this strange: we have been more wisely spending our time, first, in creating opportunities of study, too often in the face of indifference or positive opposition, until we may justly claim to have established dermatology upon a firm basis; and, secondly, in faithful observation, rather than in the preparation of crude publications, so that we have been largely ignorant of each other's opinions upon the subject. But now that the mature results of careful and extensive home observation are, of late, more generally given to the world; now that we have in our American Archives a special channel of publication, such as only one other country can boast of; and now that original and independent works on general dermatology, of which we may justly be proud, have been written by members of this Section; now is it for the first time possible to compare the results of our enlightened and independent observers with those of our foreign brethren, and to learn how far our previous vague and individual impressions are supported by facts drawn from wide fields of observation. And yet we should not over-estimate the opportunities we even now possess for the study of this question. It is to be regretted that they exist only in a few centres of observation, separated but a short distance, and in the midst of large cities with mixed populations; nor until trained dermatologists are more widely and uniformly distributed than at present, will it be possible to form a reliable estimate of the prevalence and character of skin diseases throughout our vast and varied country, or to study in a satisfactory way the variations which these affections manifest among the many races which inhabit it.

If any one of us who has had much to do with skin diseases in both hospital and private practice in our larger cities, were now asked, what are the most marked differences between these affections here and in foreign countries, he would probably reply that we miss altogether certain diseases which are either very commonly, or occasionally, met with in some parts of Europe, while others are far less prevalent here than there. Moreover, we rarely or never see here such grave forms of some affections

as are of frequent occurrence in the old world. Again, certain diseases are more common at home than abroad, or present certain modifications in type which may be regarded as indigenous. Such, I venture to think, would be the reply of all of us, as the result of entirely independent observation; and yet if we were asked for the data upon which such conclusions were based, we should have to answer that they were largely impressions, but impressions which would prove to be in the main correct, when tested by statistics. It is to determine, therefore, how reliable are our opinions upon these points, as far at least as the test is applicable, that I have brought together as many statistical reports bearing upon the prevalence of cutaneous diseases amongst us as are available, for the purpose of comparing them with well-known foreign tables. In making up this home standard, I have preferred to use materials which are the results of the observations of those of us who have had essentially the same training in dermatology, and whose nomenclature and deductions are, therefore, interchangeable, and if faulty uniformly so. They are drawn, too, from similar sources in the large cities of Philadelphia, New York, and Boston, and are therefore homogeneous in character. The figures are taken from the published reports of free skin dispensaries prepared by Dr. Duhring, in Philadelphia, by Dr. Bulkley, in New York, by Dr. Wigglesworth, in Boston, and by the writer. They represent ten thousand consecutive cases of diseases of the skin, affording thus an opportunity of contrasting the peculiarities of these affections, if such exist, in these cities, and of forming a collection as numerous, I believe, as has been tabulated for similar purposes by any one writer hitherto in other parts of the world. I have not attempted to give the complete lists published by these gentlemen, but have put down in the table only such affections as bear possibly upon the subject before us, those of most common occurrence, and the rarer forms of greatest interest. It is to be regretted that we have not the published observations of dermatologists also from our southern and western cities, so that a more completely national representation might be offered; but until our special branch of medicine attains a more independent position in these parts of our country, we must accept this restricted report as the only one at present practically possible.

In examining this table for the purpose of ascertaining if there are any notable differences in the relative occurrence of the affections therein mentioned in the cities of Philadelphia, New York, and Boston, it must be remembered that we cannot generalize too boldly from the results of such an analysis. The element of variableness in the customs of their respective populations, in professional etiquette even, and other non-apparent circumstances, which all influence the attendance upon dispensary practice, must make no little difference in the character of the diseases treated in these cities, in addition to the more noticeable matters of race, manner of living, location, climate, etc., to which we should naturally refer such variations. On the whole, it will be observed that the affections do not vary greatly in prevalence; and some of the apparent discrepancies may be easily explained. For instance, in Philadelphia, no cases of dermatitis calorica, or dermatitis venenata, are recorded, and yet there can be no question that of the first variety, at least, cases must occur; of dermatitis venenata, Boston has more than its share, perhaps because the skin clinic of the Massachusetts General Hospital draws its patients from a wider rural area than those of her large sisters, and that her encircling flora abounds more than theirs in the poisonous

species of rhus. Epithelioma is apparently unknown in New York as a skin disease, because the large surgical hospitals no doubt attract it wholly to themselves. So, too, the table fails, without doubt, to represent the actual or proportionate occurrence of lupus, because it is so commonly regarded as a so-called surgical disease. Again, ichthyosis is apparently much more common in Philadelphia, perhaps because Dr. Duhring may regard the cases placed apart by the other observers under the title Xeroderma, as merely a variety of the former disease. Other differences, however, cannot thus be accounted for. The erythemata, for example, must be less prevalent in Philadelphia, for some inexplicable reason, than in the northern cities, for but 4 cases out of the 153 were there observed. Some small part of this great variation may be owing to difference of opinion in classification regarding some of the varieties of the affection, but a small part only. Erysipelas, too, like these other acute hyperæmic processes, seems to be of less common occurrence in Philadelphia. It is in the parasitic affections, however, that

the greatest differences are to be observed. That scabies forms but .7 per cent. of the Philadelphia cases against nearly 4 per cent. in New York, and 2 per cent. in Boston; and phthiriasis only 2 per cent. in the first against 6 per cent. and 5 per cent. respectively in the two latter cities, can be easily explained on the supposition, which is thus demonstrated to be a fact, that the former's clinic derives its material from a different class than the immigrant populations which make up so largely the patients of the two seaboard cities; but this does not explain the remarkable predominance of one of the vegetable parasites over the others in Philadelphia. Tinea tonsurans is elsewhere in America far more common than the other vegetable parasitic affections, yet the table shows that in Philadelphia tinea versicolor is of more frequent occurrence than the others collectively. In the New York column there are 47 cases of tinea tonsurans, 14 of tinea versicolor, and 7 of tinea favosa; in Boston, 271 of tinea tonsurans, 108 of tinea versicolor, and 48 of tinea favosa; while in Philadelphia there are 28 of tinea tonsurans, 33 of tinea versicolor, and 1 of tinea favosa. We are less acquainted with the natural history of the fungus of tinea versicolor than with those of the other vegetable parasitic affections, and it may be that peculiarities of this sort in its geographical distribution may throw important light upon its nature.

Inasmuch as the statistics of dispensary and hospital practice afford but a partial representation of the prevalence of cutaneous affections in the whole community, I have prepared a table (Table II.) which presents more fairly their distribution amongst all classes. It shows the relative occurrence of 5000 consecutive cases at the out-patient department for skin diseases at the Massachusetts General Hospital in Boston, and of 2000 consecutive cases in my private practice there, and illustrates the two extreme classes of patients, those on the one hand mostly poor and of foreign derivation, with the characteristic affections of poverty and neglect of personal care; and, on the other hand, those who have the means and leisure to seek professional advice for troubles which more affect the looks than the health of the individual. These extremes largely represent, therefore, the affections of squalor and of luxury; but, even when the two classes are placed together, they fail to show fairly the prevalence of cutaneous diseases amongst all classes. Most infantile affections of the skin among the middle and upper classes, for instance, remain under the care of the family physician, and only in exceptional cases are seen by the specialist. This is true, too, with many of the trivial and self-limited diseases among them.

As might be inferred, it is mainly with regard to the affections which characterize the two extremes of the classes which make up this table, that we find the most striking differences. Those diseases which affect the personal appearance of the patient, and do not interfere with health and labor, are naturally in far greater proportion in private than in dispensary practice. Thus we see that acne forms 18 per cent. of the former, and 6.9 of the latter; the various forms of loss of hair, included under alopecia, over 10 per cent. in the former, and less than one-fourth of 1 per cent. in the latter; all the varieties of seborrhœa 10 per cent. of the private cases, and only 1 per cent. of the hospital cases; and yet there are no good reasons for believing that these affections are even as prevalent among the rich and well-cared for as among the poor and less cleanly. On the other hand, it is in the latter class that we find the animal parasitic affections positively more abundant, as likewise those which are

caused wholly or in part by the action of external irritation, and those which are more or less due to poverty of the blood and unhealthy ways of living. Thus disturbances produced by lice form 5.4 per cent. of the hospital cases, and only .3 per cent. of those in private practice; and scabies 2.8 per cent. in the former, and 1.4 in the latter. The various forms of dermatitis, due to the action of external causes mainly, were twice as common with the former as with the latter. Eczema, which is somewhat under the same exciting influences, formed 44.8 per cent. of the former, and 25.3 of the latter; but it must be remembered, as above explained, that the latter figures represent less fairly the absolute prevalence of eczema among the wealthy classes. Herpes formed 2 per cent. of the hospital cases, and only .6 per cent. of the private. The varieties of cutaneous syphilis, both acquired and congenital, were in the former 6.5 per cent., and in the latter 2.05 per cent. Ulcers 6.18 per cent. of the former, and only .75 per cent. of the latter. Urticaria 2.6 per cent.

of the former, and .85 per cent. of the latter. In other orders of affections, which are apparently little under the influences of class and customs of life, we find a striking equality in prevalence in the two series of cases. The erythemata, mostly forms of E. exudativum multiforme, were alike in both, 1.6 per cent.; ichthyosis .1 per cent. in the hospital cases, .15 per cent. in the private; lupus .34 per cent. in the former, .4 per cent. in the latter; psoriasis 3 per cent. in the former, 3.9. in the latter; and yet even with these affections we cannot accept these comparative results as representing absolutely their relative prevalence amongst all classes.

Let us now compare the combined results of our American table with those of similar statistics in other countries. The most available materials for this purpose are Anderson's 10,000 cases from the Glasgow Dispensary, Purdon's 3000 Irish cases, and 24,000 made up from the annual reports of Hebra's Vienna clinic; and the private cases published by Wilson and Anderson, with 2000 of my own; making 47,000 hospital and 13,000 private cases—in all, 60,000. Dr. Anderson's cases are especially valuable as representing the prevalence of skin diseases in Great Britain, not only because the number is the same as that in our American table, but because his nomenclature and classification are also essentially identical with those of the American reporters. The statistics of Wilson and Purdon are less valuable, because from want of such harmony it is impossible to make a reliable comparison of affections at all complete. On this account I have been obliged, in the following tables, to group several classes of disease under more general heads than in Table I.

Table III. shows the comparative prevalence of the more common affections of the skin in American and European dispensary and hospital practice; and Table IV. shows the same in special private practice here and in Great Britain, as closely as differences in nomenclature and classification will permit the formation of reliable comparisons.

As will be seen, Acne appears to be three times as common with us in dispensary practice as in Scotland, and nine times as much as in Vienna, if the tables are to be believed; or else our population is more sensitive about its "complexion" than foreign nations, even among the lower classes. The former conclusion is sustained in Table IV., which shows that acne forms but 7.5 per cent. of private cases in Glasgow, and 5 per cent. in London, against 18 per cent. in Boston. The Vienna statistics, it must be borne in mind, represent more a resident than an ambulatory class of patients. Alopecia, meaning loss of hair in general, forms .36 per cent. of the dispensary cases in America, .56 per cent. in Scotland, and .26 per cent. in Ireland, whilst it does not enter at all into the Vienna tables, because it is not a sufficiently serious affection for hospital residence; among private cases it forms 10.2 per cent. of the Boston, 1.8 per cent. of the Glasgow, and 4 per cent. of the London cases. Alopecia areata, on the contrary, seems to be of much more common occurrence in Scotland than here, for in the dispensary cases it forms .26 per cent. of the American, and 1.5 per cent. of the Scotch; and among the private cases 1.3 per cent. in Boston, 4.4 per cent. in Glasgow, and 2.7 per cent. in London. Of its prevalence in Austria we can form no estimate. Chloasma (the local distribution of melanoderma upon the face, moth or liver-spot, as popularly called) formed .5 per cent. of the dispensary, and 1.9 per cent. of the private cases here, against .03 per cent. of the former and .3 per cent. of the latter in Glasgow. Ecthyma presented no differences of impor-

tance, although the term is too loosely used for close comparative analysis. Eczema made 38.7 per cent. of the American dispensary cases, 25.57 per cent. of the Scotch, 26 per cent. of the Irish, and 11.9 per cent. of the Austrian; and of the private cases 25.3 per cent. in Boston, 34.8 per cent. in Glasow, and 45 per cent. in London. It does not seem, therefore, that there is any marked difference in its prevalence in Great Britain and here at home, if the figures in both Tables (III. and IV.) be considered together; and the inverse ratio established by a comparison of its prevalence in the poorer and richer classes here and abroad may be explained by simple custom, as governing the relations between general and special practice in the respective countries. The low percentage in the Austrian column may be partly explained by the fact that those affected with the milder forms of the disease do not seek hospital residence for relief, and that cases of infantile eczema are diverted to the children's hospital.

With regard to the next two affections in the tables, Epithelioma and Erysipelas, trustworthy comparison is impossible on account of variation in local custom of referring such cases to the skin or surgical departments of hospitals. The various forms of Erythema would seem to be less prevalent in America than in Europe, for here it occurred in the proportion of 1.5 per cent. in dispensary, and 1.6 per cent. in private practice, to 4.7 per-

Xeroderma	17	.85				

cent. in Scotland in the former, and 9.9 per cent. in the latter, and of 2.19 per cent. of Mr. Wilson's cases. In Austria, on the other hand, it formed only .8 per cent. of the cases in the hospital. Herpes is considerably more prevalent in America than in foreign dispensary practice, forming 1.8 per cent. of the cases here to .3 per cent. of the Scotch, .6 per cent. of the Irish, and .7 per cent. of the Austrian; but in private practice, as with eczema, an inverse ratio prevails, at least in London, the percentage being in Boston .6, in Glasgow .1, and in London 1. Ichthyosis shows no remarkable variations in the tables, .7 per cent. being the highest ratio presented by any country. Lupus, on the other hand, shows a marked difference in relative occurrence, being much less common here than abroad, a fact which is strongly impressed upon an American in Europe by the chronic nature of the disease and the heroic means employed in its treatment. Of the dispensary cases it forms in America but .6 per cent., in Scotland 2 per cent., in Austria 3 per cent.; and in private practice here .4 per cent., in Scotland 2.5 per cent., and in London 1.5 per cent. The reports do not allow a proper subdivision into its two distinct forms. Pemphigus shows itself about alike in both classes of cases and in all countries. Phthiriasis is naturally everywhere almost exclusively confined to the lower classes, and marks clearly the degree of degradation in habits of cleanliness of a nation. It will be easily understood,

therefore, why Austria with her dirty Slavonic races should present so excessive a percentage of cases, 13 per cent. to 4.8 per cent. in America, 3.3 per cent. in Scotland, and 3.5 per cent. in Ireland, although the Vienna figures comprise also the excoriations produced by fleas and bugs. Scabies, too, affords of course another and much stronger illustration of the same law. Of dispensary cases it forms amongst us only 2.3 per cent., in Scotland 25 per cent., in Ireland 16 per cent., and in Austria 48 per cent.; and in private practice in Boston 1.4 per cent., in Glasgow 4.4 per cent., and in London 3 per cent. Prurigo may be set down as an affection almost wholly absent from this country, and in fact virtually confined exclusively to certain parts of Europe. Not a single instance is recorded among the dispensary cases in America, only a single one in Scotland, whilst it forms 3 per cent. of the Austrian. In my private practice I am not sure that I have seen a single case, whilst Anderson puts down two instances in his list. Mr. Wilson's statistics cannot be considered, as he confounds the disease with simple pruritus. This latter affection seems to be somewhat more prevalent here than in Europe, forming 1.7 per cent. to .4 per cent. of the Scotch, and .6 per cent. of the Austrian dispensary cases; and of the private cases 1.6 per cent. here, to 1.1 per cent. of the Scotch, and .6 per cent. of the English.

Psoriasis is much more common in Scotland than elsewhere, according to the tables, in both classes of patients; in the dispensary cases showing 7.25 per cent. to 3.7 per cent. American, 2.5 per cent. Irish, and 2.2 per cent. Austrian; and in the private cases 10.6 per cent. to 3.9 per cent. American, and 6.3 English. Purpura, if the small number of cases recorded permits comparison, seems to be rather more common here than in Great Britain, both in dispensary and private practice. Scrofuloderma is a term so indefinitely used by different writers that no legitimate conclusions can be drawn from the statistics presented. Seborrhœa, like acne, appears to be much more common amongst us than elsewhere, the term being used to include that scaly condition of the scalp so intimately connected with alopecia. Of the American dispensary cases it forms 1.6 per cent., of the Scotch .13 per cent., and of the Austrian .1 per cent.; whilst in private practice it forms 10 per cent. of all cases. With regard to the syphilodermata, it is clearly impossible to draw any inferences from the figures presented in the tables as to the comparative occurrence of this disease, because the existence of special departments and of advertising quacks draws the cases almost wholly away from skin clinics. In the Vienna column, for instance, the space is not filled, because the number of cases which find their way into the cutaneous wards is so trivial compared with the immense number in the adjoining clinic of Sigmund. In the skin department of the Massachusetts General Hospital, the cases (Table I.) are almost wholly those of the wives and children of diseased men. The Vegetable parasitic affections present some rather surprising results: Tinea tonsurans is more common here than in other countries, forming 3.46 per cent. against 1.4 per cent. of the Scotch, 1.7 per cent. of the Irish, and .33 per cent. of the Austrian dispensary cases; and in private practice 5.6 per cent. against 3.6 per cent. of Anderson's, and of 2.5 per cent. of Wilson's. Hebra's cases hardly represent the frequency of its actual occurrence, because he did not recognize, when they were published, the parasitic character of eczema marginatum, and a portion of his cases of sycosis should possibly be included in the same class. Tinea versicolor does not vary so greatly, but is less common in Ireland and Austria than elsewhere. Tinea favosa is somewhat less common here

than in Europe, and noticeably so than in Scotland. It is in Italy, however, that it especially flourishes. The ratio which these three affections bear to one another in Scotland in dispensary practice is singular by comparison with other countries, for whereas with us tinea tonsurans forms 3.46 per cent., tinea versicolor 1.55 per cent., and tinea favosa .3 per cent., and in Ireland 1.7 per cent., .6 per cent., and .5 per cent., respectively; in Scotland the percentages are 1.4, 1.06, and 1.56, or nearly equal. In Anderson's private cases, however, their relative occurrence is more like that observed elsewhere. Urticaria is somewhat in excess in America, forming 2.65 per cent. of the dispensary cases against 1.47 per cent. in Scotland, 1.4 per cent. in Ireland, and .8 per cent. in Austria; but in private practice the difference is not so marked, the percentage being .85 in Boston, .5 in Glasgow, and .88 in London.

TABLE V. *Showing the relative prevalence of certain rare forms of skin disease in both dispensary and private practice in America and Europe.*

Diseases.	Amer'n. 10,000 dispensary cases.	Per cent.	Scotch. 10,000 dispensary cases.	Per cent.	Irish. 3000 dispensary cases.	Per cent.	Austr'n. 23,944 hospital cases.	Per cent.

Xanthoma	4	.2	......	......	8	.08

If we now turn to Table V. we may learn the relative prevalence of some of the rarest forms of disease of the skin in both dispensary and

private practice in America and Europe. The results are interesting mainly because they show on the one hand how extremely rare are certain affections of the most marked type, and on the other hand how very infrequent are other diseases in the countries thus represented compared with their well-known prevalence elsewhere. We have here tabulated, it will be remembered, 60,000 cases of skin disease. Among them in the first category we find only 4 cases of cutaneous horns; 32 cases of molluscum contagiosum, 16 of molluscum fibrosum, 15 of morphæa, 12 of scleroderma, and 16 of xanthoma. In the second class above specified the most notable instances are those affections which assume in certain parts of the globe an endemic character; elephantiasis Arabum occurs but 56 times, 36 of which are found in the Austrian column; elephantiasis Græcorum (leprosy) 27 times, of which 2 were American, 3 Scotch, and 3 Austrian, and the remainder (Mr. Wilson's) nearly all imported cases from colonial leprous districts. Pellagra occurred but in a single instance. Two other affections, outside these two classes, should, perhaps, be referred to specially, inasmuch as they have been so sharply defined as distinct types by Professor Hebra; these are lichen exudativus ruber and lichen scrofulosorum. Of the former not an instance is recorded outside the seven Austrian, except one amongst Anderson's private cases. Lichen scrofulosorum occurs only twice in the American 12,000, and five times in the Scotch 11,000 cases; while 67 instances are recorded in the Austrian statistics.

The conclusions to be drawn from the above brief analysis of these tables, which have a direct bearing upon the question immediately before us, may, perhaps be best arranged as answers to questions, as follows:—

(1) What skin diseases of well-established character and recognized occurrence in Europe are wholly absent in the United States?

(2) What affections are noticeably less prevalent here than in Europe?

(3) What affections are more prevalent amongst us than in Europe?

(4) What modifications from the European types are observed in skin diseases in the United States?

(1) *Wholly absent.*—The most notable example in this class is Prurigo. I mean by this term of course the affection which one sees so frequently in the Vienna clinic, and which is marked by such pronounced features that its individuality is unquestionable. I do not mean that jumble of cutaneous disorders so frequently called by this name, secondary changes in the tissues of the skin as the result of simple pruritus, animal parasites, etc. One feels its absence from his practice after foreign study as a positive void long after his return, but may even come in time to doubt the truthfulness of his recollections and the very existence of the affection. Not a single case is recorded among the 10,000 American cases in Table III., and but a single one among the same number in Scotland, and I am giving here the results of the observations of those only who have had ample opportunity of studying it in Vienna. In the table of statistics of private practice, Anderson records two more cases. In my own, none are set down; yet I have seen one or two patients, whose cases in Vienna might perhaps have passed for doubtful, ill-defined examples of the disease, but none who presented all its well-characterized manifestations. Dr. Wigglesworth, of Boston, has reported a case which he thought must be prurigo. On the other hand, we find in the Vienna column of the table 740 cases, forming in fact 3 per cent. of all cutaneous diseases treated in Hebra's wards. How can we account for this striking

variation in the prevalence of so well-defined an affection; for its entire absence from this country? I can offer no explanation. There is nothing in its pathology, or known etiology, to assist us in this direction. Its prevalence is greatest in the country which, of all Europe, presents the greatest diversity in races. We can only blindly congratulate ourselves on the absence of this life-long and well-nigh incurable disease.

Among the rarer affections of the skin which are tabulated as to their comparative prevalence in Table V., there are two which find no place in the American columns, lichen exudativus ruber, and pellagra. The first named is one of the rarest diseases even in the country where its individuality was first recognized and announced, only about twenty cases in all having fallen under Prof. Hebra's observation, seven of which find place in the Austrian column. Anderson records a single instance among his private cases, making, with Hebra's, only eight among the whole 60,000. We know nothing of the causes, and but little of the nature, of an affection which proved uniformly fatal until brought under subjection by arsenic, but more extended observation may yet give it a place upon our native list.

Pellagra, granting still its specific individuality, follows such sharply defined geographical laws of distribution, that it is not surprising that but a single case is recorded in the table and that under Mr. Wilson's observation. It is improbable, with the marked contrast in respect to the abundance and variety of food which our country offers to the regions infected by this disease, that it should develop amongst us, but not impossible that emigrants from its haunts may bring it to our shores. It would scarcely establish itself here, however, as it has been slowly retreating from some of its oldest footholds in Europe during the last half century.

(2) *Less prevalent.*—Our analysis shows that the following affections have more or less claim to be considered in this class: Erythemata, lichen scrofulosorum, lupus, leprosy, phthiriasis, scabies, tinea favosa, and alopecia areata.

The various forms of erythema seem to prevail less in the United States than in Great Britain, at least. The causes of such disturbances are so various and so often of extraneous character, that it is not strange that considerable diversity in their prevalence, corresponding to variations in modes of living among different nations, should exist. Of lichen scrofulosorum we know so little that it would be useless to conjecture why the skins of strumous patients should be less liable to such disorder here and apparently elsewhere than among the nations of the Austrian empire, but such is notably the fact. Lupus, it will be seen by the tables, forms one of the most striking examples of variation in comparative occurrence upon this list. It is an affection, moreover, about which false conclusions in this respect are least liable to exist; for it is so grave in character, so enduring in course, and so imperative in its demand for heroic means of cure, that scarcely a case is liable to escape the observation of the dermatologist. Lupus is a rare disease in America, although if our figures were drawn from hospital records the statistics might fail to support this opinion, because most chronic ulcerative and destructive processes, especially those seated upon the face, are regarded by surgeons as lupus. It is not only rare but, as we shall see below, modified in type also from that so commonly observed in Europe. The opinion is held, I am aware, by some American dermatologists that lupus vulgaris is even less common than lupus erythematosus amongst us. Dr.

Duhring has found it to be so here, in Philadelphia, and Dr. Geddings, of Aiken, whose valuable studies of this affection are so well known, writes me that it is "much more common at the south than genuine lupus." Yet Tables I. and II. show that whatever be the case in the more southern parts of the United States, such is not the fact when the figures drawn from the three cities, Philadelphia, New York, and Boston, are combined, for of the seventy cases forty were lupus vulgaris and thirty lupus erythematosus.

Leprosy (elephantiasis Græcorum) according to Table V. would seem to fall almost within the class of affections which do not occur amongst us, two cases only being recorded therein, both of which, however, were observed in native Americans. Yet we know that in the neighboring province to the northeast there has long been a community of lepers, and that in our western States among the Norwegian immigrants the disease exists. In our southern States, too, I am informed that it prevails to some extent, and am indebted to my friend Dr. W. H. Geddings for the following notes concerning its occurrence in his native city, Charleston, S. C. The first case of the disease came under the observation of his brother in that city some time between 1846 and 1849, but he is unable to say whether it had occurred before that time. Sixteen well-established cases have come to his knowledge since then, five of them within the last ten years. In none of them was any hereditary taint to be traced, no progenitor having been affected as far as known, except that mother and daughter in one instance were attacked simultaneously and died about the same time. In two other instances also two members of the same family were affected. These certainly are very important data, and worthy of further careful investigation in connection with the question of infection, which can be nowhere so favorably studied as in an isolated region where hereditary taint is excluded. With regard to the race and color of the lepers, four were Jews, eight were white Christians, three were mulattos, and one a full negro. The wide-spread occurrence of the disease outside our limits to the south, in tropical America and its islands, and westward in the Pacific isles, is well known. With such foci of foreign origin all around us, and even within our borders, it is not improbable that the disease may some time become endemic in the United States.

Phthiriasis and Scabies.—In the former, an affection almost wholly confined to the lower classes, we somewhat lead Great Britain, according to the Tables, but as compared with Austria, our cases are only one to three. It is in connection with scabies, however, that the most remarkable difference is to be observed. Since the close of our late war, during which it attained a wonderful growth, it has again dwindled until it has become a somewhat rare affection, even in our seaboard cities where immigration is constantly bringing fresh supplies to sustain it. While with us, as Table III. shows, it forms only 2.3 per cent. of dispensary cases, in Scotland it constitutes 25 per cent., and in Vienna 48 per cent. of the same class, and in the Ospedale di S. Gallicano at Rome, one-half the cases under treatment in 1873 were of scabies. The disease seems to be diminishing also steadily in Austria, for, whereas in the Vienna clinic in the year 1857, that of the first report included in our statistics, there were 1695 cases, in 1873 there were only 322, a diminution due in part to the fact that the various trades in Vienna are employing each its own physician, instead of sending the infected to the general hospital. There

is no reason, however, why, with habits of cleanliness like our own, the disease should not become as rare everywhere as amongst ourselves.

Tinea favosa, as stated in the analysis, is somewhat less common here than in Europe, especially in Scotland, but it is in Italy that it finds apparently its most favorable conditions of development. In the skin hospital at Rome, above mentioned, Dr. Schilling reports 145 cases in the year 1873, 93 in 1874, and 63 in 1875, or nearly 12 per cent. of all the cases there treated. Such extraordinary preponderance implies either the existence there in proportionate abundance of the extraneous sources of contagion, or wonderful carelessness or ignorance concerning its communicability. Tinea tonsurans and tinea versicolor, on the other hand, it may be stated, seem to be almost wholly unknown there. Such local peculiarities in the prevalence of the vegetable parasites, may yet lead to important discoveries in relation to their non-parasitic phases of development.

Alopecia areata.—With no intention of entering upon the disputed question of the nature of this mysterious affection, it is to be noted that it is of less frequent occurrence here than in any of the European countries from which we have drawn our reliable data.

(3) *More prevalent.*—The affections which are shown by the tables to be in any marked degree more prevalent here than in Europe are, seborrhœa, acne, urticaria, pruritus, the peculiar forms of efflorescence due to the poisons of rhus and mosquitos, heat rashes, herpes, alopecia, and tinea tonsurans (sycosis). The affections of the sebaceous glands seem really to be more common with us in all classes than among European nations. I have no explanation of the fact to offer, but I am aware that it will be used as an argument by those who hold the opinion that acne is connected with derangements of the digestive system, inasmuch as Americans are supposed to be more "dyspeptic" than other people. However this may be, for my part I have never been able to find any fault of the internal economy which I could regard as an important primary factor in the etiology of this disease in any general way. No more can I explain the somewhat increased prevalence of seborrhœa of the scalp in private practice here, over its occurrence in the same classes of society abroad, in places where our statistics allow a direct comparison. The more frequent occurrence of alopecia, as shown in Table II., is, perhaps in proportion to, and in direct consequence of, this latter affection.

Urticaria and pruritus are both slightly more prevalent in the United States than in Europe. Both are more or less intimately dependent upon modifications of innervation, and it may be that our drier atmosphere or greater extremes of temperature may account for such excess; certainly the latter affection in some of its forms is closely connected with the winter season. Summer, too, with our intenser heat, it may here be mentioned, produces far more frequently direct disturbances of the general integument than in more temperate Europe. Prickly heat, heat rash, or folliculitis dependent upon overwork of the sweat glands, is universally prevalent, leading up to acute eczematous and furuncular inflammations of the cutaneous tissues, which form no small share of our practice during such a season as the summer just passed. Herpes zoster, too, appears to be more common among dispensary patients here than abroad, possibly through climatic influences, as there are good reasons for believing that in some cases it is directly caused by impressions received through the skin itself. Other forms of dermatitis occur amongst us, which as the result of purely *local* excitants, in both senses

of the word, are not met with in Europe, but which on this very account need only have mention here. They are the peculiar eczematous inflammation produced by the poisonous species of rhus, so widely diffused throughout the United States, and the multiform efflorescences provoked by the stings of mosquitos in persons not previously inoculated with their virus.

The vegetable parasitic affections present, as we have seen, very unexpected variations in comparative prevalence in the countries included in our tables. It is tinea tonsurans which seems to find its most favorable conditions of growth amongst us; and in its various manifestations of ringworm of the scalp, beard, and general surface, of parasitic sycosis, and so-called eczema marginatum, is quite a common affection. Among domestic animals, too, it is not unfrequently observed. Were the facts of such unequal distribution of cutaneous affections more fully recognized, we should not witness controversies between dermatologists of different countries concerning the prevalence or even the very existence of certain diseases, nor have the authority of so eminent a master as Hebra categorically expressed in denial of the occurrence of affections which are almost daily met with here, because they are rarely met with in Vienna. Of such character are his assertions in relation to tinea sycosis, which may well be extremely rare in Vienna, and yet from different habits of barbers in shaving, perhaps, or from other causes, may occur very frequently elsewhere, as it certainly does at least in Boston. It is especially in connection with the vegetable parasitic affections that one's point of view should be very broad before venturing upon such statements.

(4) *Modifications.*—Before discussing this division of our subject, it should be distinctly stated that we have now left our tables, imperfect as they are, behind us, and that our opinions in connection with it rest almost wholly and necessarily upon impressions alone. As individual observers we may naturally differ widely from one another, therefore, upon such points. My own opinions will be stated, briefly and it may be uncertainly, although I doubt not that others will have much more decided and definite views upon the subject to express. I am aware, for example, that some of our best observers believe that many affections of the skin assume a more acute or inflammatory type amongst us than elsewhere, and that others are of the opinion that cutaneous diseases are less tolerant of exciting and severe local medication than in Europe, and that therefore what may be the best methods of treatment there may be injurious even, if strictly followed here. I am not prepared to concede these propositions; at least I do not think that I have sufficient evidence to warrant the statement of any such convictions in this paper, even if they were doubtingly entertained by me. That my judgment with regard to the choice of remedies in skin diseases may differ somewhat from that of some foreign writers and teachers, is indeed true, but I do not on this account feel authorized to infer that the therapeutical or physiological reaction of the American skin differs materially from that of the European, for I know that I differ quite as widely from some of my colleagues here at home upon important matters of treatment, and I must confess too that, now that I come to record formally my opinions regarding this part of our subject, I am not prepared to state my belief in the frequency or degree of such changes of type in these affections as strongly or generally as I thought I might do before considering the question so immediately.

The number of diseases that I can specify as exhibiting such modifications to any noticeable extent is therefore extremely limited. They are, moreover, diseases characterized by varied and extreme structural changes of the cutaneous tissues, so that a comparison of the appearances presented as they occur here and elsewhere, is easy. The most conspicuous example of such is undoubtedly lupus vulgaris. We have already seen that it occurs far less commonly here than in Europe, and it may be that the same law governs its course as well as prevalence. At all events, I think there can be no question that we do not see cases here which approach those so frequently met with in foreign clinics in severity of the destructive process, or in extent of the surface affected. Such at least is my own experience, and I have no reason to offer in explanation of the fact. It might seem that it required several generations of accumulated malnutrition or more positive constitutional evils to effect such eventual disorders of cutaneous structure, and that on this account lupus prevailed more abundantly and in its worst forms where poverty and bodily misery were more common than with us; but I do not think that the history of individual cases amongst us warrants any such conclusion. I wish I could add that I have found a corresponding benignity of type in its disposition to yield more readily to treatment, but corresponding classes of cases have in my experience exhibited the same obduracy to remedies here as in Europe, and perhaps the same tendency to relapse.

The same statements may be made with truth, too, in my opinion, of the cutaneous syphilides, especially their later manifestations. We rarely, if ever, see here cases of so grave a type as in European hospitals. There seems to be a resistance to the destructive force of the disease, on the part of the skin, which tends to prevent the formation of the worst lesions within its tissues.

Leprosy, too, seems to feel the mitigating effect of some local influence within our borders. In Trecadie it has kept up a lingering existence for many years. With regard to its character among our Norwegian immigrants at the West, at present, I regret that I have no definite information to impart; Prof. Boeck expressed the opinion, after his visit to them a few years ago, that the disease seemed to be partially controlled; its course retarded to some extent by their change of residence. Whether the interesting observations made by him while amongst them are best interpreted under the theory of contagion or hereditability, is not within the province of this paper to consider. As to the character of the disease, as it occurs in our southern States, I am not informed.

Indeed, the best use that I can make of my conspicuous want of knowledge upon this and other points which should be considered under this division of our subject, is to exhibit it frankly as an illustration of what, I fear, may be a too common state of ignorance on our part, and to indicate how much definite information is yet to be acquired before we can intelligently discuss it. Finally, I may add that no one can be so fully aware as myself of the incompleteness of this paper in all respects, and to how unsatisfactory an extent it fails to answer the questions it proposes. I offer it merely as an introductory sketch, or skeleton chart, to show in what directions we may best carry out the investigations which may eventually lead to the full solution of the subject.

The following conclusions seem to be warranted by the data above presented:—

I. Certain obscure affections, the etiology of which is little, if at all, understood, even in those parts of Europe to which they are mostly con-

fined, may be regarded as practically non-existent amongst us. Such are prurigo, pellagra, and lichen exudativus ruber.

II. Certain diseases, directly connected with and dependent upon poverty and habits of personal uncleanliness, are less prevalent in the United States than in those parts of Europe of which we have sufficient statistical information for comparison. Examples of this class are the animal parasitic affections especially.

III. Some cutaneous affections of grave character, which are dependent upon or a part of serious constitutional disorders, are of less frequent occurrence and of milder type amongst us than in Europe in general, or those parts of it where they are endemic. Lupus, the syphilodermata (?), and leprosy are the most marked instances of this class.

IV. Certain disorders of the skin, especially those of its glandular systems, and those connected more immediately with its nervous system, are apparently more prevalent with us than in Europe. The most notable examples of the former are seborrhœa, acne, and possibly the heat rashes; of the latter, herpes, urticaria, and pruritus.

Discussion on Dr. James C. White's Paper.

After the reading of the preceding paper, Dr. Louis A. Duhring, of Philadelphia, said:—The subject treated of in the paper just read is one of great interest, and the statistics contained in it show that there is a marked discrepancy in the prevalence of skin diseases in the three great eastern cities of this country, Philadelphia, New York, and Boston. How to account for these differences is a difficult problem, and, on account of these differences, Dr. White's conclusions should, it seems to me, be taken with reserve. The precise meaning of some of the terms employed should also be given with more particularity; for instance, morphæa is a name susceptible of several meanings.

Dr. L. Duncan Bulkley, of New York, said:—American statistics are not as complete as could be desired. Morphæa is undoubtedly more frequent than it is represented to be in the tables of Dr. White's paper. I have myself seen it in a number of cases. I observe that no cases of prurigo are mentioned in the paper. Heretofore, I have only reported cases observed at hospitals and dispensaries, and have not reported those of my private practice. I have had two cases of prurigo under my own observation in this country. I also believe that, in the types of diseases of a congestive character, there is a marked difference between this country and Europe. I have in New York repeatedly tried Hebra's treatment for this class of cases, without success. I am of opinion that in these diseases, as met with in the United States, there is the general characteristic of nervousness, so peculiar to the American people, which requires a treatment very different from that taught in the schools of Europe. American physicians are discovering this every day; they are becoming more familiar with American characteristics as they grow older, and are finding it profitable to forget much that they learned in the old world.

Dr. Duhring said:—I have brought up the subject of morphæa in order to ascertain the views of Dr. White on that disease. Dr. White and Dr. Bulkley evidently understand it as Mr. Wilson has described it; whereas I think that Mr. Wilson has so confounded it that no one could recognize it from his definition as a distinctive disease. Mr. Wilson confounds the old morphæa of leprosy with the modern morphæa. I have discarded the definition of Wilson, and also that of Kaposi, and have from experience adopted the view to which Dr. Fox has inclined. Morphæa should be entirely disconnected from leprosy. I have seen three cases of it, at a clinic in London, and five in this country. As I understand the disease, its manifestations are of two kinds; the first being the large or small yellowish circumscribed patch upon the skin, like

a piece of fat or lard, in appearance resembling the well-known macular form of leprosy, with which, however, it has no connection. Another form entitled to the name of morphæa is the keloid so accurately described by Dr. Addison. I have seen four cases of this disease in this country. It is an extremely complex affection, requiring great detail and particularity in its description. I have seen all the symptoms encountered in both forms of the disease in one patient; I have seen the macular patches from the size of a pin's head to that of a hand with those numerous symptoms of the so-called keloid of Addison. I have also seen the macular manifestations, accompanied by reddish or purplish streaks and striæ atrophicæ, and, moreover, band-like cicatriform lesions. In a paper recently prepared by me, I have tried to give an accurate description of the disease, but to attempt it here would occupy too much time.

Dr. BULKLEY said:—I would designate as morphæa just what Dr. Duhring has described, and, with due deference to Dr. Duhring, would say that Wilson gives a similar description.

Dr. DUHRING said:—Partial atrophy of the face should not be confounded with morphæa, though it closely resembles the cicatriform form of the disease. The subject is a very complicated one, and the clearest distinctions should be made between the old morphæa of leprosy, the macular and cicatriform varieties of the disease now designated morphæa, and unilateral atrophy of the face.

Dr. WHITE said:—I had a case which began with the round form of morphæa. It was sent to England where Mr. Wilson saw it and called it morphæa; then to Vienna where Hebra called it Addison's keloid; and, finally, returned to this country and resulted in time in atrophy of the skin. In the paper before the Section the word has been used in all the looseness of meaning requisite to cover the variety of forms assumed by the disease.

Dr. DUHRING said:—I have seen the case referred to by Dr. White, and I would call it unilateral atrophy of the face. The lesions are not confined to the skin, but extend deeper and affect even the muscular tissues and bone substance. In one case of unilateral atrophy of the face which I have observed for eight years, the tongue and roof of the mouth have dwindled upon one side to only half the normal size.

Dr. BULKLEY said:—I have seen two such cases, in which the patches, or arrests of development, resembled very much morphæa. I have also within a few days seen a patient who has been put under galvanic treatment and is two-thirds or three-fourths cured.

Dr. DUHRING said:—In the reported cases of unilateral atrophy of the face, the disease has tended to increase from year to year, while in those cases of morphæa which have come under my observation, the disease has tended to spontaneous recovery; one young lady who has been the subject of a most extensive morphæa, is now nearly cured, the patches upon her body having undergone spontaneous involution; this never occurs in unilateral atrophy of the face.

Dr. WHITE said:—With regard to prurigo, I am well aware that many English writers do not concede that there is such a disease, maintaining that the cases seen in Vienna are but poorly developed diseases of a secondary character, in which the cutaneous lesions follow, and do not antedate, the subjective features.

Dr. BULKLEY said:—I have seen two well-defined cases of prurigo in native Americans. One occurred in a man who, after terrible suffering, died of the disease. The other was the case of a child.

Dr. S. ENGELSTED, of Copenhagen, said:—Prurigo is very rare in Copenhagen, but is sometimes met with. It sometimes commences in childhood, and is then incurable. It occurs only in the lowest grades of the population.

Dr. DUHRING said:—I agree with Dr. White, that this is a very rare disease. I have seen but one case in this country (at Boston), that I thought was prurigo; I could not positively say that it was so, for I saw the case only once, but if asked to name it I could call it nothing else. I was forcibly struck with its resemblance to the Austrian prurigo. The whole surface was involved.

While attending the clinic at the Hôpital St. Louis, at Paris, I one day saw a boy who had prurigo. Hardy said that he called the disease "strophulus prurigineuse," but it was undoubtedly the prurigo of Hebra. Hardy said it was obstinate but curable. Evidently it did not, in Paris, take on that aggravated form which is commonly seen in Austria. There is at present, in the Philadelphia Hospital, a case very much resembling prurigo, but I would not so call it. I doubt whether lichen ruber is more common abroad than here. Lichen planus and lichen ruber I regard as one and the same disease, the latter being the more advanced stage of the process; I would ask Dr. White whether, in his experience, he has ever known lichen planus to run into lichen ruber?

Dr. WHITE said:—I have not.

Dr. DUHRING said:—I would ask Dr. Engelsted whether he has ever seen in Copenhagen Hebra's lichen ruber?

Dr. ENGELSTED said:—I have not, but I have seen there lupus vulgaris.

Dr. DUHRING said:—Lichen ruber is as rare in Europe as here. I have seen in this city a case of lichen planus which passed into what might be called lichen ruber; it was not so severe as the cases I have seen abroad. Prurigo is a common disease in Austria, but lichen ruber is rare. I must also differ from Dr. White as to the severity of the syphilodermata, which I consider to be as severe in type in this country as in Europe.

Dr. WHITE said:—Upon this point I have written only from my own observations in Boston of the severity of the disease, and have made no comparisons with other cities.

Dr. ARTHUR VAN HARLINGEN, of Philadelphia, said:—I agree with Dr. Duhring that Philadelphia has a pretty fair share of these cases, and that many of them are of a severe type. There are no syphilitic clinics in this city; but, judging from the tables of skin diseases, the proportion of the syphilodermata is large.

Dr. BULKLEY said:—I coincide with Dr. Duhring's opinion that the disease is not less severe here than in Europe.

Dr. DUHRING said:—Many cases have come to my notice undiagnosed and consequently untreated. I can recall half a dozen frightful cases which have come from the country districts untreated. In Vienna the disease is, as a rule, recognized at once and treated, and hence it is checked before it reaches its worst stage. One case which I can recall had been diagnosed as cancer, and so treated for fifteen years.

Dr. BULKLEY said:—I have known five cases of elephantiasis Græcorum; two died within four or five years; another has been progressing eight or nine years, and another four or five years. Two of these cases came from the southern part of this continent. Those which occurred in native Americans were very severe.

Dr. DUHRING said:—I was not aware that leprosy occurred in this country at all unless it was imported. Before being convinced that it exists endemically, I should like to see a case thoroughly studied by a competent observer and have it carefully reported. The disease occurs in Central America and Mexico, in the Sandwich Islands, and also in California; but not, I think, endemically. I have seen but one case in this country, and that was a Cuban, who acquired it probably in Spain.

Dr. WHITE said:—Prof. Boeck thought that the disease, as found in the Norwegian settlement in this country, had been checked by the change of residence. I have known of one other case, one of the tubercular form of the disease, which resulted fatally in Boston.

Dr. VAN HARLINGEN said:—As to lupus, I think that statistics here show a larger proportion of cases of lupus erythematosus than of lupus vulgaris; in fact, the former may be considered a common disease, whereas the latter is not so frequent.

Dr. DUHRING said:—The American type of lupus vulgaris is much milder than the European.

VERRUGAS, A DISEASE PECULIAR TO PERU.

BY

GEORGE A. WARD, M.D.,

MEDICAL DIRECTOR OF THE OROYA RAILWAY.

[COMMUNICATED BY THE SECRETARY.]

IT is, I believe, pretty generally know throughout the world that Peru is engaged in the gigantic enterprise of building a series of railways across the snowy peaks of the Andes, in order to connect the Pacific ports with the head waters of the Amazon; and by this means to establish a shorter communication with Europe, thus avoiding the inconveniences which now result from a long and tiresome sea-voyage, as well as throwing open to the world the untold wealth which exists on the Amazon and its tributaries. This wonderful undertaking, conceded to be the greatest engineering triumph of the century, is due to the energy, skill, and perseverance of Don Enrique Meiggs.

On one of these routes, starting from the Pacific Ocean at the port of Callao; passing through Lima, the capital of Peru; thence up the valley of the river Rimac; and finally crossing the summit of the Andes by means of a tunnel, at an altitude of 15,645 feet above the sea-level, vast obstacles have been encountered, not only in the way of the many natural difficulties to be overcome, but also from many and strange diseases, one of which it is the purpose of this paper to describe; but before doing so, a brief geographical description of the district in which this disease prevails will be proper.

This district lies between altitudes of 3000 and 6500 feet, cases of the disease occasionally originating a few hundred feet higher, though rarely. In and about San Pedro Mamma, 3000 feet above the sea-level, we find arid dry rocks; but on the river banks, wherever water has access, fine pasturage for animals. The banana here grows luxuriantly wherever cultivated; as we gain altitude, we encounter fine groves of oranges, figs, cherimoyer, peaches, guavas, and in fact every variety of tropical fruit except the cocoanut; as well as vegetables familiar to our northern eyes, such as the onion, lettuce, cabbage, etc. At an elevation of 5280 feet, and 46 miles from the sea, the character of the soil changes, as the valley becomes more narrow, the soil sandy and intermixed with granite, the sides of the mountains steep and producing abundantly a variety of cacti, but still susceptible to a high degree of cultivation wherever water can be carried. At an elevation of about 6000 feet, we find the granite in a friable, decomposing condition.

Running through this valley is a rapid mountain stream varying in depth from two to six feet, and fed by springs and the melting snows of the summit. The temperature at the altitude of 3000 feet is mild and equable; as we gain 4000 feet the temperature is increased, and at an altitude of 5280 feet we frequently encounter a temperature of 110° Fahr. in the shade, in the middle of the day, and at night find it sufficiently cool to require a couple of blankets on our beds, the range of

temperature frequently being as great as forty degrees Fahr. between 12 M. and 12 P.M. Approaching an altitude of 6000 feet, the temperature again becomes more equable, and at an altitude of 8000 feet it rarely varies ten degrees the year round.

The name popularly applied to the disease of which I am about to speak is VERRUGAS. It is a disease usually preceded by an initial fever of varying intensity, lasting from ten to thirty days, and accompanied by excruciating pains of a rheumatic character, finally culminating in an eruption of warts over the body; these occasionally proceed to suppuration and ulceration, accompanied at times by profuse hemorrhage.

It is a disease confined to certain valleys in Peru; it has well-defined limits, and is not found outside of those limits. Its range of altitude is between 3000 and 6500 feet, and it is found in the valleys of the Rimac, Pacasmayo, Chimbote, and some of the valleys on the eastern slope of the Andes, and was probably the disease which struck terror into the adventurous hearts of Pizarro's troops on their march into the interior of Peru through the valley of Tumbez. I am informed that this disease prevails on the eastern slope of the Andes, but always under the same conditions of altitude, soil, climate, and natural productions.

It is a disease which affects animals as well as men; it is a disease which recurs, one attack not exempting from a second, a third, or even a fourth, if the person is exposed to the same influences. The eruption, however, in the subsequent attacks, is not as profuse, nor the warts as large as in the first, although no general rule is observed in this respect. The disease obeys none of the known laws of the exanthemata, although it is in many respects closely allied to them. Retrocession of the eruption always produces very grave, and often fatal, symptoms, and usually takes the form of congestion of the liver or lungs. In like manner, should the eruption not make its appearance on the skin, or mucous membrane of the mouth or nose, a fatal termination of the case may be expected. Many have supposed the disease to be allied to syphilis, but I do not so regard it. The disease cannot be communicated by inoculation, for I have repeatedly tried on my own person, as well as on others, the insertion of pus from an ulcerating verruga, but without avail. The only analogy with syphilis is in the nocturnal pains and the occasional persistence of a copper-colored spot on the skin after a large verruga has proceeded to ulceration and cicatrization. The ulcers lack, however, entirely the geometrical forms so characteristic of syphilitic ulcerations, and these copper-colored spots are only left on the parts of the body which are covered by the clothing; no matter how large a crop of verrugas one may have had on the face, scars or discolorations rarely remain.

In those cases in which the disease is heralded by an initial fever, two types are presented; the acute rheumatic, and the low typhoid, often combined with an intermittent element which prevails extensively in the verruga district. Patients thus affected require careful watching from their extreme liability to succumb to the violence of the fever, before the eruption makes its appearance.

In the excruciating pains, particularly affecting the joints, this affection is closely allied to dengue, a disease which occasionally occurs in the Southern States of North America. In contradistinction to dengue, however, one attack does not prevent another; the fever has a longer duration; the eruption is of a different character; hemorrhage only

occurs from the verruga itself; the duration of the disease is much longer; it is not epidemic; and it is an extremely distressing and often fatal disease. It occurs as well among the strong and healthy as among those who are weakened by previous disease, or who are of feeble habit of body.

In regard to the cause, nothing is known. Many have supposed the disease to be caused by the water of the valley; this cannot be the case, as many people have simply passed through the infected district on horseback, or in the train, without drinking one drop of water, and have been as severely affected as those who have passed weeks and months in the valley. Others, in their fear of having the disease, have drunk nothing but wine or brandy during their entire period of residence, even refusing coffee and tea; and have suffered just as severely as others who have followed their ordinary mode of life. Some suppose that it may arise from the turning up the ground along the line of railway, thus bringing certain telluric influences to bear; this, however, cannot be the entire cause, as the disease existed before the ground was ever disturbed. I am inclined to the opinion that the friable, decomposed, and decomposing granite, has an influence in producing this disease as well as the intermittents which here prevail to so great an extent. I have known a nursing infant pass one night in the affected district, and in three weeks break out over the entire body with verrugas. The disease may not show itself for weeks or months after exposure, though a change of climate, and particularly a sea-voyage, is very liable to bring out the eruption.

I remember particularly the case of an Italian, who had made some money on a small contract in the infected district, and, returning to his home in Italy, on the voyage, broke out with verrugas; on arriving at his home he was immediately ordered into quarantine as a leper, and was not allowed to enter the city until he had been pronounced cured by the proper authorities. Many of the gentlemen connected with the railroad, when home on visits to New York, California, or other parts of the world, have been looked upon with very grave suspicion, not only by their friends, but by physicians and surgeons whose word is law in regard to medical matters.

The treatment of the disease is entirely palliative, and will be more particularly illustrated in the typical cases presented. The bowels should be kept open by mild laxatives, of which none are better than the tamarinds taken freely in the form of a drink; the infusion has a grateful, subacid flavor, particularly agreeable in the semi-febrile condition of the patients, and the addition of one of the alcoholic stimulants will usually be advisable. Should there be indications of liver trouble, nothing is better than blue mass or podophyllin. Hot vapor baths, or a resort to any of the various hot springs, will have the effect of accelerating the appearance of the eruption. I have sometimes found good effects from the iodide of potassium, in ten grain doses three times daily, taken in an infusion of sarsaparilla, or, more agreeably still, in the compound syrup of sarsaparilla of the U. S. Pharmacopœia. Should the pain be so great as to prevent sleep, morphia or chloral must be resorted to. The blood is thinned, and deficient in hæmatin; hence the necessity for the use of iron, and, of all the preparations of this metal, I have found none to equal the muriated tincture, given in ten drop doses, three times daily, in a glass of port wine. This course of treatment, with a full generous diet, and a proper allowance of alcoholic stimulants, will usually

in time bring out the much desired crop of verrugas. Exercise in the open air, although exceedingly painful and at times impossible, is of very great importance.

A great variety of native remedies has been used in this disease. I have tried them all and found them all wanting. Of these remedies, the best is an infusion of the Indian corn, taken in large quantity with the native sweet wine of the country. This "agua mote," as it is called, has a diaphoretic and diuretic action, as have in a greater or less degree the other native remedies, "uña de gato," "maguey," "norvillo," etc. All of these remedies are taken in infusion, and with an equal quantity of sweet wine.

Should none of these measures avail to bring out the eruption, a change of climate or a sea-voyage, or a resort to some of the famous warm baths of Chili, will probably have the desired effect.

The literature of this disease is very scanty. Prescott, in his Conquest of Peru, mentions it as one of the diseases encountered by the Spaniards. Von Tschudi, in his work published in 1749, mentions it, and the same author is said to have written an article on the subject in some medical journal of Germany; these, with an article in a Lima newspaper, and an article by Dr. J. M. Browne, U. S. N., in the Contributions to Medical Science, U. S. Navy Department, vol. i., 1872, constitute, I believe, the entire literature of the disease. An idea of verrugas can best be formed by the study of illustrative cases, of which I cite a number, and, as will be observed, the symptoms in the various cases are diametrically opposed to each other, scarcely any two cases presenting the same features.

CASE I.—The first case of verrugas which I ever saw was in the northern part of Peru, on a sugar hacienda. The patient presented himself to me with what I supposed to be a node, just on the point of ulceration. I immediately placed the man upon a course of iodide of potassium and iron, advising rest, and poultices to the tumour which was situated upon the edge of the tibia. This, however, did no good, and the tumour, after ten days' treatment, showed no signs of ulceration or pus. One day the superintendent happened to see it, and without ceremony plunged in a lancet, making a gash about an inch long, and then sent immediately for me to control the hemorrhage which his unlucky thrust had caused. I succeeded in this by using pressure and the perchloride of iron; rapid ulceration then took place, and the man left the hacienda and went to a hospital in Lima. About a year afterwards he came under my observation in one of the hospitals of the line, suffering from caries of the tibia and continued fever, of which he died. Upon questioning him, I learned that before going to the hacienda he had been at work on the Oroya Road, and that he had thus contracted the disease there.

CASE II.—A Chinese had received an injury of the spine, causing paralysis of the lower extremities, and had been in the hospital for a period of about five months, slowly but steadily gaining the use of his legs. One morning he called my attention to some lumps on his legs, about as large as peas. These lumps gradually increased in size and number, without pain, heat, or redness, until many of them reached the size of hens' eggs, and till they were found not only on the legs but on the arms and chest. The patient in the mean time did not suffer the slightest inconvenience whatever, not one of the verrugas proceeding to ulceration, but gradually subsiding as they appeared. His appetite remained good, his urine was free and of natural color, and his bowels acted daily and naturally. The only remedies given were the tinctura ferri chloridi, ten drops three times daily, and a daily subcutaneous injection of the fiftieth part of a grain of strychnia, which remedies were given for the

paralysis. I saw the patient frequently for two years afterwards; he was in good health and condition, and with only a slight degree of paralysis remaining.

CASE III.—This was the case of a Chinese who entered the hospital with all the symptoms of rheumatic fever, complaining of pain in the joints, which were swollen and tender, his tongue being covered with a dirty-white fur, his bowels constipated, and his urine scanty and high colored, at times not more than half an ounce being secreted in the twenty-four hours, and that soon becoming nearly solid from the contained urates. The fever was constant, the pulse ranging from 110 to 120 in the minute, and the temperature from 102° to 104° Fahr. The patient was placed upon the alkaline course of treatment for rheumatic fever, with some slight improvement to the symptoms. Diuretics, however, produced but little effect upon the urine, and after having exhausted all the means at my command, and, at the end of two weeks, the patient's condition continuing much the same, I resorted to a native remedy, which consisted of an infusion of the legs of the common cricket. Four of the legs of the cricket were bruised and infused in half a pint of hot water, and when cold half an ounce of the infusion was given every four hours. This produced immediate relief to the symptoms; the urine began to flow freely, and there was an immediate abatement of the febrile movement, followed by a profuse eruption of verrugas which proceeded rapidly to ulceration accompanied by free hemorrhage. The ulcers finally healed kindly under the use of the carbolated cerate and powdered matico. Iron and alcoholic stimulants were freely used to recuperate the patient's strength, which was much exhausted by his long and painful illness which had extended over a period of three months.

I was led to the use of the infusion of cricket legs by the recommendation of Dr. H. Kinney, former Medical Director of the line, who highly extolled it as a diuretic. I have used the remedy a number of times since, and with uniformly good results. I do not pretend to explain its modus operandi, but presume it to be analogous to that of cantharides, as in one case I observed some tendency to strangury.

CASE IV.—My own case. I was attacked with wandering pains about the body, just one month after taking up my residence in the infected district; these pains particularly affected the joints, sometimes one and sometimes others, the pains simulating those of muscular and articular rheumatism, but without the inflammatory symptoms. These pains were of an intermittent, shifting character; for instance, they would affect one joint, say of the little finger, in the morning, and by noon would be located in the opposite hand, knee, leg, or arm, and as rapidly change to other parts of the body, affecting, however, particularly the legs below the knees. Suddenly all the pain left the extremities and located itself in the right testicle, which became enlarged and exceedingly painful, though without any inflammatory symptoms being developed. All the ordinary remedies useful in swelled testicle, excepting leeches, were used to mitigate the pain and reduce the swelling, but without avail; but the swelling, which had come on rapidly, after continuing for nearly two weeks, subsided within twenty-four hours, leaving no ill effects behind. Immediately, however, the right arm began to swell, and continued to do so until I thought the skin would burst, so great was the tension; the tumefaction extending from the fingers to the shoulder, and lasting for about ten days, then subsiding as rapidly as it had come on.

During this time I was in perfect health, being able to ride about on horseback, eat well, and drink well, wandering pains, however, being felt throughout the body, as well as the steady pain in the arm. After the subsidence of the swelling in the arm, there was a let-up to all the symptoms, but this was only the calm before the storm. Suddenly I was prostrated by congestion of the liver, followed by jaundice and the discharge of a large gall-stone, which brought me so near death's door that my coffin was actually prepared. Fol-

lowing this, appeared the eruption of verrugas over the entire body, and a sea-voyage restored me to health. The first pains were felt on the first of March, and the first verrugas showed themselves about the first of August, when they continued coming and going until December, many of them ulcerating and being the source of free hemorrhage.

The course of treatment which I adopted was simply palliative, treating each symptom as it arose. My diet was of the most generous description, accompanied by the free use of brandy and wine, and I continued to go about and attend to my professional duties, though at times the effort was most agonizing from the intense pain. I gave a thorough trial to the corn-water with sweet wine, but did not perceive that it had much more effect than would naturally be induced by the ingestion of a large amount of fluid.

I have since that time had three other attacks of the disease. In the second attack I suffered no pain; two or three verrugas made their appearance on the skin, and a severe wetting caused their retrocession, producing extreme irritation of the stomach, which was only relieved by a residence at the sea-side and a careful use of iced champagne. In my third attack, three verrugas, the size of pigeons' eggs, made their appearance without any premonitory symptoms, causing no pain or inconvenience. Business compelling me to make a long and tiresome journey on a hard-trotting horse, which, considering that I had been out of the saddle for three months, was anything but agreeable, a violent congestion of the liver and lower portion of the lungs resulted, and was followed by the retrocession of the verrugas and a narrow escape from death. In my fourth attack I suffered but slight pain, the eruption making its appearance over the entire body, but none of the verrugas being larger than a pin's head. I am now in the most perfect state of health imaginable.

This disease is particularly liable to attack the mucous membranes; I have repeatedly seen verrugas coughed from the throat and lungs, and have found them in the intestines after death. Should a verruga locate itself upon the eye, it should by no means be disturbed, and only the simplest remedies should be used to combat any sympathetic irritation, allowing nature to take her own way to cure the disease. Troublesome cases occur occasionally in which the verruga locates itself in the urethra, causing mechanical obstruction to the passage of urine. The treatment is obvious; the patient must urinate, and hence a catheter must be passed, and retained if necessary, with a bandage upon the catheter to restrain hemorrhage.

ARE ECZEMA AND PSORIASIS LOCAL DISEASES OF THE SKIN, OR ARE THEY MANIFESTATIONS OF CONSTITUTIONAL DISORDERS?

BY

L. DUNCAN BULKLEY, A.M., M.D.,

PHYSICIAN TO THE SKIN DEPARTMENT, DEMILT DISPENSARY, NEW YORK, ETC.

THE suggestion of a local pathology of diseases of the skin is of comparatively recent date, and stands in bold contrast to the older humoralistic doctrine, which ascribed all these diseases to a morbid entity, a *materies morbi*, seeking exit from the system, and whose escape is beneficial; and the positive demonstration within the present century of a local cause of several cutaneous maladies (as dermatitis, the parasitic affections, etc.) which had, for ages, been regarded as expressions of blood states, is an achievement of which modern medicine may justly be proud.

This discovery of a local origin of certain skin lesions, and the fact of the resemblance between some of the forms of dermatitis and the eruptions of impetigo, lichen, eczema, etc., have led some to claim, still further, that most, if not all, of the diseases affecting the skin are either the results of local external causes, or are local diseases originating in idiopathically deranged action of the elements of the skin; a view, the adoption of which has undoubtedly been promoted by a natural reaction from the too exclusive, humoral doctrines previously entertained.

It need hardly be said that in arguing a constitutional origin and nature of eczema and psoriasis, I do not desire at all to return to the older humoralistic doctrine of disease, but seek to keep entirely within the bounds of recent chemical physiology and pathology, while at the same time I by no means ignore the importance of local cell-action, as will appear later. Nor does the recognition of a constitutional nature of eczema and psoriasis, by any means necessitate a belief that it is dangerous to check or remove these diseases by local measures, for experience has proved the contrary; it does, however, demand an investigation of internal causes, and a removal, as far as possible, of systemic disorders, since thereby elements of disease are removed and the general system benefited, while the eczema and psoriasis are cured.

In the further presentation of the subject of the nature and origin of eczema and psoriasis, it will be advisable to separate the two diseases more or less; I will, therefore, in each instance speak first of eczema, and then make the application to psoriasis; because, although they resemble each other in many important particulars, and have many points of contact, their dissimilarities are such as to cause confusion if they are in every instance spoken of together.

The local pathology of eczema and psoriasis has rested largely on three grounds: first, on the results obtained in the local treatment of these and other diseases of the skin, especially in the larger hospitals in Europe, notably those in Vienna; second, upon microscopical researches in histology; and, third, as far as relates to eczema, on a clinical and micro-

scopic study of the artificial eruptions produced on the skin by irritating substances, idiopathically and experimentally. We will dispose of the last of these first.

Now, while there is as yet no absolute proof that the pathological process excited artificially in the skin differs essentially from that taking place in acute eczema, we need not conclude that eczema is of local origin because its eruption resembles artificial dermatitis. If we accept one artificial eruption as eczema, we must accept all as such, from the large blisters following cantharides, heat, and cold, to the discrete, pustular eruption caused by croton oil or tartar emetic, or the slight erythema of the mildest irritant. Moreover, many of these artificial eruptions resemble erysipelas even more than they do eczema, and yet there will be few who will hold that true erysipelas is a local disease of the skin; again, the eruptions of croton oil and tartar emetic resemble those of smallpox and syphilis, without this being any argument against the constitutional nature of these latter, while the eruptions produced by the insect in scabies and by lice are frequently confounded with eczema. These lesions are all purely local, there is simply a local response of the cells and capillaries of the over-stimulated part; they are all but forms and varieties of inflammation of the skin, and are properly termed dermatitis, and bear no more relation to eczema than does the inflammation of a sprained joint to true rheumatism. In a very small proportion of persons, such irritations may become the starting point of true eczema, but in them I believe that the elements of the eczematous diathesis may always be discovered. A demonstration of the essential difference between these artificial eruptions and eczema is shown by the fact that it is not uncommon to induce dermatitis, as by a blister, for the cure of chronic eczema, as also of psoriasis.

It is necessary, therefore, in the present study to remember the distinction between eczema and dermatitis, for undoubtedly much that has been treated for the former is but the latter, and of course no argument can be drawn from therapeutical results obtained in dermatitis as to the local nature of eczema. In regard to psoriasis also, we have to clearly exclude, not only the scaly syphiloderm, but also all syphilitic influence; true psoriasis, the lepra of Willan, has nothing to do with syphilis, not even in the way of a later hereditary transmission, as has been suggested, nor must it be in any way confounded with the dry, scaly forms of eczema, or with the true leprosy, the elephantiasis of the Greeks.

Before proceeding systematically to examine the several points regarding the local or constitutional natures of these diseases, let us consider, for a moment, the question of the possibility of a double origin of the diseases under consideration, whether they can own two natures, being sometimes local and sometimes constitutional. In regard to the skin lesions in the contagious exanthemata and syphilis, no question exists that their origin is solely and always due to the introduction of a poison, which acts through the system, and that the cutaneous manifestations are but one exhibition of their effect. Passing now to such general diseases as gout and rheumatism, whose etiology is more deeply hidden, we do not doubt that the local phenomena observed in each are always the result of the same constitutional condition, some of the earlier links in the chain of cause and effect being recognized in functional derangement of certain organs, and a consequent sub-oxidation or imperfect elaboration of the elements of food, and an absence of healthy disintegration of tissue; and

when we speak of cold or external injury as being the cause of gouty or rheumatic inflammatory action in a part, we understand readily that it is only intended to signify that it was the *exciting cause*, which determined that that particular spot should be affected, or that the disease should develop at that particular time. The same line of thought might be extended to other diseases, showing that it is irrational to deny the constitutional origin of a disease unless its local nature can be established in a manner answering every requirement, as is the case in the parasitic diseases of the skin; quite as impossible is it to exclude local causation, when the constitutional nature fails to account for every condition.

Great error has, therefore, been made, I believe, by those who look only or mainly at the local causes, and argue therefrom a local nature of eczema, they forgetting the established principles in general medicine in regard to predisposing and exciting causes of disease. This is verified by the fact of the difficulty of producing a true eczema artificially, at will, in a person not subject thereto either in self or family (if indeed it can ever be done), and the impossibility of inducing a psoriasis by any local means.

Our conclusions then, thus far, are that eczema and psoriasis cannot be both local and constitutional diseases, that is, either exclusively, according to the case; and that the eruptions resembling eczema, artificially produced, are either ordinary dermatitis, with a strong tendency to spontaneous recovery, or are true eczema in eczematous subjects, in whom the exciting cause, instead of occurring in the ordinary way, has been artificially supplied, just as a gouty person might, by measures voluntarily applied, induce a true gouty inflammation of a joint. As before stated, we know of no claim to the production of psoriasis by local measures alone.

In the present study of the question as to whether eczema and psoriasis are local diseases of the skin or manifestations of constitutional disorders, I propose to develop the following points:—

(1) The nature of the eruption in disorders of the skin which are recognized to be constitutional, as the contagious fevers, syphilis, etc., drawing a comparison between eczema and psoriasis and these affections, and showing their points of difference.

(2) The nature of local diseases of the skin.

(3) The microscopic anatomy of eczema and psoriasis, with a view of comparison with that of the local skin diseases on the one hand, and with that of the constitutional on the other.

(4) The clinical history of eczema and psoriasis, in so far as they bear on the question, the points considered being (*a*) age, (*b*) sex, (*c*) location of eruption, (*d*) relapses, (*e*) hereditary transmission, (*f*) gouty and rheumatic symptoms, (*g*) urinary disturbances, (*h*) bronchitis, etc.

(5) The clinical history of some local diseases, to show the differentiating elements between constitutional disorders and those believed to be local, as epithelioma, verruca, keloid, parasitic and mechanical diseases of the skin, etc.

(6) The effect of local treatment, and how far the success of local measures necessitates a belief in the purely local nature of the disease.

(7) The effect of constitutional treatment, and the internal and general measures of service in eczema and psoriasis, to show how far their effect proves that the diseases which they remove are constitutional.

(1) In comparing eczema and psoriasis to the acknowledged constitutional disorders affecting the skin, contagious fevers, syphilis, etc., we must not, of course, press the similarity too far. We find, however, certain resemblances, as in the symmetry of development of the lesions, for eczema, if uninfluenced by local causes, will, when carefully studied, be found to exhibit this almost as clearly as psoriasis, whose bilateral disposition is so striking; the peripheral mode of spreading of eczema resembles much that of erysipelas, and the scattered eruption of psoriasis corresponds much to the mode of development of other exanthematous diseases, including syphilis. Eczema also is not infrequently attended with fever, in its more acute and general forms, and on the full, recent development of psoriasis there is more or less of malaise and prostration, and probably fever. The characters of the lesions in eczema and psoriasis are not entirely unlike those of constitutional diseases, which are marked by, first, congestion; second, exudation; and, third, if these former have been sufficiently severe, desquamation. The lesions of eczema and psoriasis are also superficial, and rarely, if ever, do they leave cicatrices, when uncomplicated.

(2) In contrast with these stand the characteristics of local diseases of the skin, marked by their utter want of symmetry (unless accidental), their extension depending either on a recognized cause, or being unexplainable, as in keloid, epithelioma, etc.; local diseases very rarely affect the whole integument, or even large portions, unless ichthyosis, of whose true nature, however, we know very little, be granted as such. Local diseases, moreover, acknowledge no constitutional connections nor fever; while, finally, the congestive element of eczema and psoriasis stands in striking contrast to its absence in local diseases, except, of course, where it is called forth by local stimulation. I am well aware that many cases of eczema present a number of the features of local disease, and that psoriasis occasionally is seen quite localized; but this is the exception, whereas it is rare to find exceptions in regard to the local diseases exhibiting any constitutional features; and, as we have concluded that eczema and psoriasis cannot be at one time local and at another constitutional, the weight of evidence, in this comparison, is decidedly in favor of the latter.

(3) The study of the microscopic anatomy of eczema and psoriasis is as yet in its infancy, and throws but little light on the etiology of these diseases; but, for a comprehensive view of the subject, we will briefly recall the main points in their histology, which will be seen to favor the constitutional rather than the local nature of the affections. The first anatomical change in eczema (reasoning from what is observed in artificial eruptions) is capillary congestion, resulting in capillary stasis and exudation in the tissue of the skin, producing more or less œdema. In some instances, not rare with us, the process stops here, or is arrested by treatment, and we have only the erythematous state, followed by moderate desquamation, the result of the impaired nutrition of the outer layers of the skin, a state very similar to the epithelial shedding in scarlatina, erysipelas, or measles.

If the exudation is too great to allow of absorption, it seeks egress through the external layers of the skin, or becomes organized as chronic infiltration. Biesiadecki believes that the fluid of eczema gains exit through certain spindle-shaped cells, which lie between the round and polygonal cells of the rete, these becoming so altered as to convey the fluid, as through direct channels. When the outer surface is still intact,

the hard, horny epidermis resists further progress and a vesicle forms; when the epidermal layer has been dissolved off or ruptured, the fluid oozes from the surface. Charpy[1] gives a somewhat different account of the genesis of eczema; still regarding the beginning of the disease as being in the corium, and consisting in a congestion of the layer just beneath the papillæ, he believes that the exuded fluid is absorbed by the deeper cells of the rete, in the intervals between the papillæ; that these cells become engorged until they rupture, whereby alveoles are formed; and that the increase of these alveoles terminates in the production of vesicles, upon the rupture of which cul-de-sacs are formed, whose walls furnish the further secretion.

In chronic eczema, the exuded plasma has become organized, and is seen as cell infiltration of the corium; the papillæ are much enlarged; the lymphatics, both in the papillæ and corium, are increased in size and dilated (Neumann); the bloodvessels are sometimes obliterated (Rindfleisch); and even the deepest parts of the skin are involved.

The anatomical and other relations of eczema have suggested to some a likeness between this and catarrh of the mucous membranes, and it may be well here to consider for a moment the nature of the mucous affection called catarrh, in reference to the bearing of this resemblance upon the nature of the diseases now under consideration. First, it must be remembered that it is no more proper to call all inflammations of the mucous membranes catarrh, than it is to name all those of the external integument eczema, or even dermatitis; the term catarrh but signifies the exudative feature, and the word eczema implies much the same. We have already separated and clearly differentiated many diseases of the mucous membranes, and it is highly probable that future study will show that there are many very different processes included in what is yet called catarrh, and ultimately their nature and origin will, we suspect, be as clearly defined as are now those of cutaneous diseases, or, it is hoped, far more clearly. That this is true may be judged from our present knowledge; thus, we have simple intestinal catarrh caused by the direct irritation of indigestible substances, a mechanical affair corresponding to ordinary dermatitis; we have an incontrollable diarrhœa, or catarrh, from the irritation caused by the circulation of effete substances in renal disease; there is also a mechanical catarrh from portal congestion in cirrhosis; we have also gouty affections of the various mucous surfaces; likewise the catarrhal complications of measles, those of syphilitic origin, etc., and I have long believed that much of the ordinary bronchial catarrh was truly eczema of that surface. Therefore, in likening eczema to catarrh of the mucous membranes, we by no means simplify matters in regard to its local or constitutional nature. Moreover, the common observation of catarrhal affections following a chilling of the surface, does not indicate necessarily their local nature, due wholly to the cold, for we see great differences in the results produced, dependent evidently upon constitutional states, the congestion due to the action of cold on the integument being only the exciting cause.

We will now consider for a moment some views in regard to the local nature of eczema propounded by Dr. Tilbury Fox, in the Lettsomian Lectures for 1869 and 1870.[2] He suggests that the capillary congestion is a *consequence* of cell-activity, arguing that mere capillary excitement

[1] Annales de Dermatologie et de Syphiligraphie, t. iii, p. 100.
[2] Eczema, its Nature and Treatment; London, 1870.

cannot give rise to eczema, because otherwise the erythemata would constantly overstep their limits. The element of the influence of the nervous system is largely considered by Dr. Fox, who believes that this abnormal state of the cells may be in response to "perverted innervation," as suggested by Hebra some time since; but while Hebra limited the action of the nerve influence to the production of "congestion and other disturbances of the circulation," Fox considers its influence in inducing cell proliferation a very necessary point to be admitted in eczema. That the latter is very true is shown by alterations of tissue plainly following and due to nerve lesions, and the same might be expected from the distribution of the nerve fibres even to the cells of the rete and epidermis.

But while a step in advance is made in recognizing the direct agency of the cell elements of the skin in the production of eczema (and independent cell activity can be no longer denied, as is shown in leucocytes), and while the influence of the nervous system in the production of cell changes is acknowledged, there is no proof that this cell change is really primary in eczema and psoriasis, and independent of constitutional conditions, and that it exists as a local affair; and this view finds little support beyond theory. It is a field, however, in which research is needed, and may perhaps be carried on with advantage, namely, the microscopical investigation of the apparently healthy skin of markedly eczematous subjects, both before and after local disease, as also a study of its nervous relations, both clinically and histologically. Should repeated, careful, and well verified microscopic studies demonstrate cell change in the earliest erythematous stages of eczema, and possibly also in the elements of the skin of eczematous patients before or after disease, it would do much to enlighten what otherwise must remain uncertain, namely, the part that the diseased tissues take in eczema, how far they are primary and how far secondary. The skin is the most favorable, if not the only, portion of the body on which very early pathological changes can be observed and followed, and research in this line may throw light upon the pathological histology of other organs.

That independent cell-action has much to do with inflammatory and other changes in the skin, is evident from the results of mechanical and chemical irritation, where, as in the case of the ordinary blister, the intervention of any blood influence cannot be suggested with reason; and that the cells are under very direct control of the nervous system is also very plain from the lesions in zoster, elephantiasis Græcorum, those occurring after nerve injuries, etc.; here the cells which under normal nerve control absorb just enough nutriment to maintain their proper relations, under perverted nerve control take on morbid action. Anatomical studies of the nerve trunks and branches in eczema might perhaps assist in our knowledge of its nature.

Psoriasis has been less studied microscopically than eczema, and little or nothing has yet been published of its genesis. The most striking histological changes in sections from older patches, as is known, consist in a great papillary enlargement, with thickening of the rete Malpighii to a corresponding extent, or nearly so. The papillæ are crowded with new cells, disposed mostly about the bloodvessels, with some infiltration of the corium; but the infiltration is not nearly as extensive as in chronic eczema, as might be judged from the clinical appearances.

Wertheim, from a microscopical study of psoriasis, concluded that the patches were due to some peculiar change in the capillaries of a circumscribed spot. Neumann considers that what Wertheim thought were

enlarged and blocked-up capillaries were cell groups around them, but offers no suggestion as to the mode of origin of the patches. By the kindness of my friend Dr. A. R. Robinson, of New York City, I have had the opportunity of examining microscopically some sections from psoriasis, which confirm Wertheim's views, and throw some light on the pathological histology of this disease. The earliest specimen was taken from a papule of psoriasis but two weeks old, in which there had been but little scaling. The bloodvessels in the papillæ were very distinctly seen to be greatly enlarged, and in some places appeared to approach the surface of the epidermis very closely; in quite a number of places the bloodvessels had ruptured, and microscopic ecchymoses were plainly visible. In specimens from rather older patches the bloodvessels showed very distinct budding processes, and some of the vessels appeared completely blocked up; there was little or none of the new deposit of cells described by Neumann, and there was no possibility of mistaking the enlarged bloodvessels for cell heaps around them.

It will be thus seen that the microscopic changes in eczema and psoriasis do not differ so very much from those observed microscopically in some other chronic skin diseases, and that histology contributes but little to show the local nature of these diseases, except so far as relates to the studies of Wertheim, further verified by those of Dr. Robinson; and yet here no one can show that even those changes in the bloodvessels are primary. Fox, however, believes that psoriasis "consists primarily and essentially in a misbehavior of the cell-elements themselves—a perversion of the ordinary cell-life of the epidermis—a true tissue disease, in which the trophic nerves probably play the chief part," but, unfortunately, gives no reasons for his interesting supposition.

While this latter view finds little or no support in anything that has yet been reported of the pathological histology of psoriasis, there is a very slight foundation for it in a certain resemblance which can be made out between psoriasis and a disease of well-recognized local nature, namely, epithelioma, to which we would venture to devote a few words.

The elements which have suggested the comparison between the two diseases are: a similarity in some of their clinical features and modes of development, their anatomical disposition, the transformation of patches on the tongue, called psoriatic, into epithelioma, the asserted family relations of the two affections, and the occurrence of epitheliomatous growths on the faces of young persons affected with psoriasis. In regard to a similarity in their mode of development, the increase in both is by peripheral extension, to the extent often of forming a ring, with healing within. Anatomically, epithelioma is an outgrowth, or rather an ingrowth of epithelial elements, whether the more external ones of the skin or those lining glands; we have, as yet, no studies with which I am acquainted to prove it, but the true pathology of psoriasis may be an epithelial hyperplasy of somewhat similar nature, and the lengthened papillæ seen in it may be the result of the ingrowth of the rete. We have the same shedding of the outer epithelial layers in psoriasis as in epithelioma; on scraping both, by no means forcibly, not only are the outer dried layers removed, but the softer and more succulent portion next above the papillæ is also separated, and we have in both the bleeding, familiar to all. The presence of the fibrous papillæ in psoriasis prevents further progress in the scraping, or we might induce a destruction similar to that in epithelioma.

The only real histological support I have to offer to sustain this

theory of the ingrowth of the epithelial layer in psoriasis, other than the well-known increase of the inter-papillary portion of the rete, is found in some of Dr. Robinson's sections, in which, in addition to the capillary change already alluded to, the sheaths of all the hairs showed outgrowths at their lower portions similar to those which have been observed in lichen ruber.

The transformation of what has been called lingual and buccal psoriasis into true epithelioma is now proven beyond doubt; of the true nature of the former affection, and its relations to ordinary psoriasis, however, we have little reliable information; it is certainly rare to find these mouth lesions in psoriatic patients, and many who have them have never had ordinary cutaneous psoriasis, and it is highly questionable if there is the slightest relationship between them.

Gaskoin affirms very confidently the hereditary relations of psoriasis and epithelioma. I have occasionally found both diseases in the same families, in intelligent private patients, but have never been able to satisfy myself of any relationship; the cases, however, have been far too few, and the time which has elapsed since I first investigated the connection, far too short, to form any conclusions therefrom. I have recently treated a young man with well-marked psoriasis, who exhibited perfectly developed epithelioma in front of the left ear. I would suggest this relationship between psoriasis and epithelioma as a profitable field for research, clinically and microscopically. If a relationship can be established, the local nature of the former may be demonstrated; for the present, however, this is not proven, and the constitutional relations of this disease, as well as of eczema, are so abundant and conclusive that we must here grant them the weight of argument and fact.

(4) We will now turn to a consideration of the constitutional relations of eczema and psoriasis, as exhibited in their clinical history. In regard to the age at which they occur, eczema affects all, from the cradle to the grave; none are too young, none too old to suffer from it. This is more the character of constitutional than of local disease; cancerous affections seldom, if ever, are seen in the young; warts (of the ordinary variety) seldom in the old; keloid very generally in middle life, both extremes being spared. The vegetable parasitic diseases rarely occur in the old; whereas in them are found changes in the skin, and diseases therefrom, not seen in young life. Psoriasis may be also said to prevail at all ages, though less frequently very early or very late in life.

Eczema and psoriasis both occur about as frequently in the male as in the female. In location, eczema spares no part of the surface, and, I believe, may affect every portion of the mucous membrane as well, while its development is very commonly symmetrical; these features are true also of psoriasis, and are those of general and constitutional diseases rather than of those of local nature. The tendency to recurrence in the same parts might be claimed as a local feature, but, in regard to eczema, the same exciting cause may be present again and again; and it must be conceded that tissues are undoubtedly weakened by disease, and more likely to be affected the second time than sound tissues; this is observed in gout and rheumatism, as also in affections of the mucous membranes.

But relapses in eczema and psoriasis furnish more indications of a constitutional than of a local nature, for fresh attacks of eczema are very commonly found to follow a depression of vitality; and I believe that this is true of psoriasis far more commonly than is generally conceded. Moreover, these eruptions by no means occupy the same locations each

time. I have frequently observed that the spots of psoriasis fall almost if not quite as often on new tissue as on the sites of a former disease.

There is no doubt as to the hereditary character of eczema and psoriasis. Whether the heredity consists in any general, constitutional habit, or whether it is simply a transmitted tendency to tissue-change, cannot be shown at the present time; in favor of the latter may be cited the transmission of mental and physical characteristics, cancerous disease, and ichthyosis; as instances of the former, we have the inheritance of syphilis, gout, and rheumatism, and the history of the occurrence of gouty, bronchitic, hepatic, and urinary troubles in the family of eczematous and psoriatic patients, in such a way as to show a connection.

If the claim of an inherited, perverted tendency of tissue could be established in eczema and psoriasis, which tendency lies dormant until called into activity by some exciting cause, it would still fail to explain alone why a cause which is at one time inefficacious, will, on another occasion, even in a much less degree, be sufficient to produce the disease.

This brings us to the study of the gouty and rheumatic symptoms, the urinary disturbances, and the bronchitis of eczema and psoriasis. That patients with these affections are the frequent subjects of the systemic derangements connected with or tending toward gout and rheumatism, as well as to the complete manifestations of these diseases, is very certain; this observation is of ancient date, and is strikingly confirmed by recent science. It is not very uncommon to find attacks of gout alternating with those of eczema and psoriasis, and clinical study shows that various disorders which may properly be classed under the name of functional derangements of the liver are very common in the subjects of these two diseases of the skin.

These systemic disorders are shown in the urine, which undergoes functional derangement in a large proportion of the cases of eczema and psoriasis. In a recent contribution to and study of the subject by the writer,[1] the following conclusions were reached: "Eczemic patients seldom pass large amounts of urine, the tendency being to scanty secretion, almost always unnaturally acid, with a specific gravity averaging above normal. Free uric acid, the urates, and oxalate of lime, abound; sometimes oxaluria is very persistent. Albumen is rarely seen. The urea and uric acid are often below the normal standard, although they may be in excess when a large portion of the integument is affected; indican has been found in pathological quantities. When the specific gravity is high, it may be due to an increase in the sulphates. The chlorides are diminished. Psoriasis sometimes alternates with phosphatic urinary deposits in gouty subjects. The fixed salts are increased. The urine shows generally a hyper-acidity, with deposits of uric acid, urates, and oxalate of lime, the contrary being the exception. The specific gravity is liable to great and unaccountable variations."

It may be claimed that these urinary changes are observed in persons also with no cutaneous disease, and that therefore there is no connection between the two. I am not yet in a position to prove exactly what changes in the urine necessarily accompany eczema and psoriasis, but mention those that have been actually observed to show that patients with these diseases are not in the perfect health often claimed for them, and, although a casual examination will often fail to detect any disease other than that of the outer integument, I assert that searching investiga-

[1] Archives of Dermatology, October, 1875, p. 1.

tion will seldom fail to demonstrate elements of disordered health, very commonly shown in the condition of the urine. And as these are removed by appropriate remedies, the eczema and psoriasis improve, and *vice versâ*.

Not less striking, as indicative of the constitutional relations of eczema and psoriasis, is the occurrence of bronchitis and asthma, conjointly or alternately, in the patient, or in his immediate family; the truth of this is well attested by many writers.

The neurotic relations of eczema and psoriasis are also very interesting, and indicate other than a local nature of the disease; but the subject is yet too recent and unsettled for more than a mention in this place: I have elsewhere[1] given a fuller study of it. Recorded facts, based on large clinical experience, are needed greatly for the full and satisfactory determination of many of the points here alluded to.

(5) Enough has perhaps already been said in reference to the clinical history of local diseases, but a few points may be again alluded to with advantage in connection with what has just preceded. No constitutional relations have been recognized, to my knowledge, in any of these; constitutional remedies have no effect upon them. Their unsymmetrical character and irregular development have been mentioned, as also their removal solely by local measures. Local diseases of the skin of external origin are represented by the parasitic affections and dermatitis; idiopathic misbehavior of cells is exemplified by epithelioma and keloid; herpes zoster may be taken as a type of an acute local disease of the skin dependent on nerve elements; and ichthyosis of a chronic, local disturbance of general cell nutrition; the clinical history of each of these is familiar to all, and quite different from those of eczema and psoriasis.

Hebra, as is well known, has always stood as the representative of local pathology and therapeutics, and it may not be uninteresting or unprofitable to refer briefly to his present views in regard to the purely local nature of eczema, as found in the recent, second edition of his work.[2] That I may not be charged with misunderstanding him, I will quote a section from the close of the long chapter on the Etiology of Eczema (p. 462). After repeating what had been said in the former edition to show the local nature of the disease, and after stating his disbelief in any diathetic cause, he says: "While, therefore, we cannot accede to any peculiar or proper dyscrasia, we must, on the other hand, confirm the fact that certain conditions of the human organism, partly transient, partly permanent, at one time increase, and at another time diminish its susceptibility to agencies producing eczema. These physical conditions are called a disposition, or predisposing cause, *momentum disponens*, to distinguish them from the direct exciting cause of irritating agencies, and we are obliged to recognize these elements in the etiology of eczema, because experience confirms it."

"For example, we see an eczema on the hands and forearms of a young girl who has been engaged in washing soiled linen, and we declare that the origin of the eczema is in the action of the lye, soap, hot water, and friction. Now, at the same time with this girl, there are many other females washing in the same lye, using the same soap, and living under the same circumstances, without acquiring eczema. Indeed, this

[1] Archives of Electrology and Neurology, November, 1874, and May, 1875. Reprinted by G. P. Putnam's Sons. New York, 1875.

[2] Lehrbuch der Hautkrankheiten, Zweite Aufl.; Erlangen, 1874.

very girl, who now has eczema, has been exposed to the same influences previously without becoming affected. What is the cause of her present susceptibility? A careful examination of her general condition will give the explanation. The girl who before was healthy, robust, and regular in her menses, has now lost her appetite, has become sluggish and languid, her appearance is pale and bloated, her menstruation is profuse; in a word, she has become chlorotic, and thereby eczematous. The remedies suitable for the chlorosis are now employed; the appetite and power of work return, the menses become regular, and the eczema disappears in spite of the continued influences of the agencies causing it. The same observation is made in reference to pregnant and nursing women; also in those suffering from chronic sexual disturbances. The latter must always be looked upon as favoring elements (a *momentum disponens*, or predisposing cause) which induce a *status minoris resistentiæ*, and allow an otherwise ordinary skin irritant to become an exciting cause, a *momentum excitans*."

After again claiming that we need no blood explanation of eczema, Hebra adds: "In order not to be misunderstood, we will, however, here again state that every eczema is not caused by a local irritation, but that it may be occasioned by diseases of the rest of the system."

Such clear and unqualified statements as to the constitutional nature and origin of eczema are unexpected from one so prominently known in connection with local pathology, and show that his opinions have latterly undergone considerable change. It must be remembered, however, that at the time of the first edition of Hebra's work, upon which his reputation as a local pathologist greatly rests, many of the crude theories of the past had not yet been completely overthrown; and also that within his experience many diseases which had formerly been considered constitutional, had been demonstrated to be purely local, as scabies, the vegetable parasitic diseases, plica polonica, etc., and that the success of local measures seemed to demonstrate to him that other affections were also local; he has, however, the candor to acknowledge his mistake.

(6) We come now to one of the most interesting and at the same time most disputed portions of our investigation, namely the relative effects of local and constitutional treatment as indicating the nature of eczema and psoriasis. Hebra and Neumann declare, in the most positive terms, that it is quite unnecessary to regard the constitutional relations of these diseases, except when they are striking, and those who have followed the Vienna School for any length of time can testify how completely this idea is carried out there. External remedies and measures are used there almost exclusively, it being the greatest exception to have any questions asked in regard to the general health; and internal medication, it may safely be asserted, is very rarely, if ever, employed in the hospital, in eczema and psoriasis, except by way of experiment; and yet these eruptions are removed in a very satisfactory manner. Does this, however, prove the local nature of the disease? In negation of this I need but suggest how the stiffness resulting from gouty and rheumatic inflammation is benefited by external counter-irritants and passive motion, while the origin of the serous inflammation and fibrous thickening is recognized as of constitutional origin. Syphilitic iritis may be subdued by atropine alone, and tubercular laryngitis receive great benefit from topical treatment; the ulcers of dysentery may be cured, and the discharge of leucorrhœa arrested, by local measures; and yet these diseases be manifestations of constitutional states.

But there is not the slightest influence exerted by local treatment in preventing the return of eczema and psoriasis, whereas we know that constitutional measures have considerable power to prevent relapses; this is, as is well known, less true of psoriasis than of eczema, but mainly, I believe, because of the neglect to carry out faithfully the proper measures for a sufficient length of time after the disappearance of the eruption. Again, in this country at least, local measures often fail to accomplish the desired end until constitutional measures are resorted to in addition. In considering the effect of local treatment as an argument for the local nature of eczema, it is well to bear in mind the distinction drawn early in this paper between dermatitis and eczema, for many cases treated as the latter disease are entirely local in character, the result of local irritants, possessing in themselves a strong tendency to heal when the irritating cause is removed and the inflamed surfaces protected, that is, are cases of dermatitis and not of eczema.

I believe true eczema and psoriasis to be constitutional states wherein ordinary irritants give rise to inflammatory changes in the skin, which form an important element of the disease, but which are no more its sole element than are the cutaneous phenomena of the exanthemata, leprosy, syphilis, etc. I believe also that single attacks of eczema, and of psoriasis, too, correspond in nature very much to those of such diseases as gout and rheumatism, in which the local changes have a greater or less tendency to self-limitation, although the effects of the disease may long remain. That is, as arthritic, pulmonary, or cerebral symptoms appear to be the culmination of blood-processes which we know as gout and rheumatism, so eczema and psoriasis are directly dependent upon somewhat similar, although as yet little defined, blood changes, the acute symptoms corresponding to those of rheumatism and gout, while the chronic local alterations in the skin answer to the gouty concretions on and in the synovial membranes, and to the rheumatic thickening of the valves of the heart or around joints long inflamed; and, as in gout and rheumatism, there is a tendency for the attacks to recur again and again, the health in the mean time seeming to be perfect, so in eczema and psoriasis the local phenomena may be manifested from time to time, without any very apparent constitutional disorder between, while the *product* of the disease, the cell infiltration, remains.[1]

Now but little can be done to arrest the acute phenomena of eczema by local means, other than soothing applications, and it is very difficult to check a developing psoriasis by outward measures; but the *results* in both may be removed by local stimulants, which induce cell activity within the bounds of health. I speak more especially of these diseases in adults, for infantile eczema exhibits more plainly the constitutional elements whose great activity renders local measures often very futile.

While, therefore, the arguments are against eczema and psoriasis *being* local diseases of the skin, it must be admitted that they *become* local diseases in their skin lesions, and as such may be amenable very largely to local treatment, as far as relates to the single manifestations of disease at any one time.

(7) Whatever may be the views of those who hold exclusively to the value of local treatment in eczema and psoriasis, no doubt whatever exists in my own mind, nor, as far as I can learn, in the mind of a large

[1] "The Management of Eczema," by L. Duncan Bulkley, M.D., Trans. Am. Med. Association, vol. xxv. 1874, p. 121. Reprinted. G. P. Putnam's Sons, 1875.

share of those who make skin affections a special study, that constitutional measures are both valuable and necessary to the cure of most cases of these diseases. And by constitutional treatment I do not mean arsenic alone, nor any one specific remedy, for truth demands the acknowledgment that specifics for diseases do not exist, unless it be with the two exceptions of mercury for syphilis and quinine for malaria. But by constitutional treatment I understand the employment of every measure for the cure of disease, which cannot truly be called local treatment.

Now my experience has been, as already stated, that most patients with eczema and psoriasis present anomalies in their urinary secretion, and in proportion as this exists have I found the congestive feature of the disease to be marked, and in the same proportion have I seen the diseases benefited by cathartic and diuretic remedies. A not inconsiderable number of patients with eczema and psoriasis are habitually constipated, and the diseases, with me, resist all local and other measures until this is remedied. Many are what is called bilious, and nitric acid will do more to cure their skin diseases than any other means. It is not at all uncommon, in this country, to find eczema and psoriasis in those who are extremely nervous, and cases are constantly met with where an enormous mental strain is keeping up the disease; here the constitutional measure of rest, with perhaps change of scene and climate, is imperatively demanded, together with nerve tonics of various kinds. In dispensary practice in this city a good portion of all eczematous and psoriatic patients exhibit the features known as strumous or scrofulous, and are more quickly and surely cured by the internal administration of cod-liver oil than by any other remedy, local medication either being used not at all, or playing a very unimportant part. Arsenic also is capable of entirely curing, that is, removing, eczema, and that tolerably quickly, *without the use of any local measures whatever*, as I have repeatedly witnessed and elsewhere shown,[1] and its power over psoriasis is acknowledged on all sides. Iron is indicated in a large share of our eczematous and psoriatic patients; others require such remedies as rhubarb and soda; and the vegetable tonics play an important rôle in our therapeusis.

Diet, hygiene, exercise, and bathing, are all essential in my opinion to a successful management of these diseases. I claim that patients who have been thus carefully managed not only recover from the individual attack under proper local measures much more quickly than when the latter alone are used, but that they most certainly are in a better condition to resist future attacks, and that relapses are far less frequent, and I claim that the clinical history of the patients shows this. The action of these measures is not local, is not directed to the skin; but by virtue of the influence exerted on the general economy, as well as on the affected tissues, they cure the diseases in question.

In this study I have not referred much to the opinions of writers on dermatology, because, with the exceptions which I have mentioned from time to time, the opinion is very general that eczema and psoriasis are constitutional disorders. By a constitutional disorder, as we now understand it, is not meant the existence of some peccant material or *materies morbi*, which the system endeavors to throw off; nor that the discharge

[1] Trans. Amer. Med. Assoc., vol. xxvii. 1876, p. 163; New York Med. Journ. Aug. 1876, p. 113; Reprint, "The Use and Value of Arsenic in the Treatment of Diseases of the Skin." New York, Appleton, 1876.

is in any way curative or beneficial to the system; nor that the removal of the cutaneous lesion can in any way or manner act prejudicially to the economy; but the expression, constitutional disorder, is understood in the same sense in which it can be applied to gout, rheumatism, chlorosis, leucocythæmia, scorbutus, etc. And it is used here in especial distinction from local disease—that is a pure and specific disease of the tissues of the skin itself, singly and alone—as the artificial eruptions, parasitic diseases, epithelioma, verruca, keloid, etc.

There are several elements of causation in infantile eczema which have not been touched on, partly because of want of time, and partly because observations are wanting as to their true effects in producing the disease. One is the occurrence of the exanthematous diseases; it has been observed by some that eczema followed soon upon these affections, and it has been thought that they left such an impression upon the cell-elements of the skin that these readily took on eczematous action, simply on the application of an external irritation. Now if they can have any causative effect in eczema, the exanthemata can also induce psoriasis, lichen, urticaria, etc. Whether, however, they act in any other way than as depressants, leaving the body and tissues in an enfeebled state, I cannot tell; it will be remembered that Mr. Hutchinson has recently claimed that the later lesions of syphilis are but the remains of the earlier, general, dermal phenomena. If the exanthemata had any real power to impress any tissue change on the skin, which should afterwards result in eczema, we could hardly conceive why this should happen in such a small proportion of cases; for, of the multitudes who go through these inflammatory skin affections of childhood, but few suffer from eczema afterwards; while many children have eczema long before undergoing one of the exanthemata. We cannot therefore accept any argument as to the local nature of these diseases drawn from the previous occurrence of the exanthemata.

Vaccination is another process which we not rarely see followed by eczema; do we suppose here a local cause (other than exciting), that is, does it induce any change in the cells of the skin whereby they are more prone to eczema? I believe not, because of the very general adoption of vaccination, and the very few cases of eczema immediately following. I need not in this presence state that there can, of course, be no blood-poisoning, no contagion of eczema by means of the lymph, even when taken from a vaccinifer suffering from eczema; we know of no transmission by this means except that of syphilis, unless it be a tendency to carbuncular inflammation, of which I have observed a number of cases, and which my friend, Dr. Frank P. Foster, tells me he occasionally meets with. The only agency which vaccination can exert in calling forth an eczema, is, I believe, simply that of a local irritant, acting in the same way as a burn or other excessive stimulation. I have seen psoriasis of a very marked character develop for the first time immediately after vaccination, but the event must of course be looked upon as a coincidence, or else we must conceive that the local tendency to cell-proliferation has furnished the starting-point, the fire which kindled the train all ready for ignition. The rarity of the observation of psoriasis immediately following vaccination shows the correctness of this view.

Equally useless and uncertain is it, in my judgment, to look upon dentition in any other light than as an exciting cause, not acting locally, it is true, but probably as a reflex irritation, and as such I believe it to be of more or less importance; but in view of the small proportion of teething

infants who have eczema, and the infinitely smaller ratio of those with psoriasis, other elements must be looked to for the real etiology of these diseases; this is shown also by the frequent occurrence of these diseases in those of older years, and before the teeth begin to appear.

Erroneous diet, however, I consider as an all-important and undoubtedly prolific cause of eczema in infants, a point which we cannot here enter upon, except to mention it as of weight in favor of the constitutional origin of the diseases under consideration.

That local causes are of very great importance in the etiology of eczema in infants, as well as in adults, is beyond doubt; such causes are the use of irritating diaper-linen, harsh bandages, too frequent and careless washing and drying, incautious exposure of the face to cold air, hot caps on the head, harsh attempts to remove the dried sebaceous matter from the scalp, etc.; but that the disease very frequently does not get well upon the removal of these irritants, and under local measures alone, is certain, and that a proper study and direction of constitutional measures will cure the disease, if proper local treatment is employed, is equally sure.

Psoriasis is observed so rarely in those of very tender years, that no conclusions can be formed respecting it; if indeed the disease in infants differs in any way from that of adults.

I have said nothing yet in regard to the relations supposed to exist between scrofula and eczema and psoriasis. This is a very difficult subject and one which needs clearing up, there being thus far no sufficient data upon which to base a scientific investigation of the matter; for, although many authorities state that there is a connection, the evidence of any causal effect is far from being established. Neumann states that among 308 eczematous children he found but 30 who were rachitic and 70 who were scrofulous, while among more than 3000 scrofulous and rachitic children he found none with eczema.

For the proper study of this relation, we need to have the true position of scrofula more clearly defined than at present, its causes and symptoms more sharply drawn, and further statistical details, such as those of Neumann, recorded. That quite a share of children with eczema, among the poor, exhibit some of the features called scrofulous, that is pale, pasty skins, light hair, eyes, and complexion, enlarged glands, ophthalmia, otorrhœa, etc., is not to be questioned, but, that this state has any special effect in causing eczema, other than its depressing power, cannot now be proved. It is certain, however, that eczema and psoriasis exhibit somewhat different features when occurring in these subjects; the tendency to pus formation is evident in the secretion from eczema, and in psoriasis the scrofulous state is shown by a thickened and more yellowish condition of the scales.

Although less commonly thought of, there is probably more connection between what is called a scrofulous state and psoriasis than there is between the former and eczema. Gaskoin thinks that phthisis plays an important part in preparing the way for psoriasis, and I have been rather inclined to think the same; investigations are, however, needed here.

The results of this inquiry as to the local or constitutional nature of eczema and psoriasis may be summed up in the following propositions:—

I. Eczema and psoriasis are diseases *sui generis*, and are not to be confounded in any way with other states; as, the former with artificial

dermatitis, and the latter with the eruptions of syphilis, scaly eczema, or leprosy.

II. Eczema and psoriasis cannot own a double, independent causation, or nature, at one time local, and at another constitutional; but, with other diseases, they may have a twofold cause, namely, a predisposing and an exciting.

III. Eczema and psoriasis in many of their features resemble the accepted constitutional diseases more than they do those recognized as local.

IV. The skin lesions of eczema and psoriasis, as also their microscopical characters, more nearly resemble those of the general and constitutional diseases affecting the skin, than they do those of purely local diseases.

V. Eczema is very properly likened to catarrh of the mucous membranes, but no argument as to its local nature can be drawn therefrom; it is very probable that some proportion of the mucous attacks called catarrh are eczema and psoriasis of this tissue.

VI. Both eczema and psoriasis resemble gout and rheumatism, in certain respects, and are dependent upon a somewhat similar, although as yet unknown, constitutional cause; much of the skin lesions, as ordinarily observed, must be looked upon as the *local results* of the diseases, removable by local means.

VII. There as yet exists no microscopical or physiological proof that eczema and psoriasis are the sole result of local cell disorder, either congenital, acquired, or due to perverted nerve action; although from our present knowledge of independent cell activity, and from the intimate connection between nerve elements and the cells composing the skin, it is highly probable that cell action and nerve influence are important factors in eczema and psoriasis.

VIII. Local causes play a very important part in the etiology of eczema; they are probably inoperative in psoriasis.

IX. Certain relationships between psoriasis and epithelioma have been claimed, which require much further investigation; at present they are not established, and are no proof of the local nature of psoriasis.

X. The clinical history of eczema and psoriasis furnishes much evidence of constitutional relations, mainly with states allied to gout and rheumatism; no direct causal connection has yet been demonstrated between the scrofulous state and eczema and psoriasis.

XI. Local treatment alone is often insufficient to remove the lesions of eczema and psoriasis, and cannot prevent or delay relapses; its success does not demonstrate the local nature of these affections.

XII. Constitutional treatment, alone and singly, can cure many cases of eczema and psoriasis, and prevent or delay relapses in a certain proportion of cases; by constitutional treatment is intended every agency not properly placed among local measures.

XIII. The total weight of evidence and argument is that eczema and psoriasis are both manifestations of constitutional disorders, and not local diseases of the skin.

In closing this paper, already far exceeding the limits designed, the writer would beg indulgence for its imperfections, of which he is fully aware; some of these have been necessitated by the vastness of the subject and the small amount of space afforded in which to consider

them. Many points which had been elaborated much more, have been necessarily condensed or omitted, and many fields, an investigation of which would have further developed the subject, have been left entirely untouched; many have been barely alluded to, because of the scantiness of reliable data. It is to be hoped that the investigation will be pursued still further, for the etiology and pathology of these diseases may be considered as at the foundation of all dermatology, and the importance of some of the questions here raised can scarcely be overestimated.

The following are some of the points requiring further study: the mode of the formation of vesicles in eczema, and the way in which the exuded liquid reaches the surface; the state of the skin, histologically, very early in eczema and psoriasis, as also after the disappearance of the disease, and likewise of the skin of those subject to eczema and psoriasis in places where no disease has yet appeared; the nerve relations of these diseases clinically, and the state of the nerves microscopically; the condition of the bloodvessels very early and very late in these diseases, especially in regard to Wertheim's view of a capillary change being the cause of psoriasis; the resemblance between psoriasis and epithelioma, clinically and microscopically, as regards also the development of what are called psoriatic lesions of the mouth into epithelioma, and the true nature of the former and their relation to psoriasis, if any; also the possibility of the origin of psoriasis in hyperplasy of the rete downwards between the papillæ; the urinary relations of eczema and psoriasis, also their heredity, as relates to the diseases themselves, and also to other constitutional manifestations; the asserted connection between the eruptions of the exanthemata and eczema, especially in infants; the influence of dentition in the production of eczema; the effect of vaccination; and, finally, the relations of scrofula to eczema and psoriasis.

THE VIRUS OF VENEREAL SORES, ITS UNITY OR DUALITY.

BY

FREEMAN J. BUMSTEAD, M.D.,

LATE PROFESSOR OF VENEREAL DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE question, the discussion of which I have the honor to open to-day, is expressed in the following terms:—"THE VIRUS OF VENEREAL SORES, ITS UNITY OR DUALITY."

In presenting this question, the first inquiry that suggests itself to one's mind is whether it is identical with the question of the "Unity or Duality of Syphilis," that, for the last twenty-four years, has excited so much interest and discussion in the medical world. I reply that it *is* essentially the same. To ignore this fact, to attempt to assume a new departure, to consign the question of "unity or duality" to the tombs as having no bearing upon our present views, would be a fraud upon medical history and a source of confusion to the student; since those who have so earnestly advocated the so-called "duality of syphilis," have never for a moment supposed that there existed two kinds of syphilitic virus, but merely that there was more than one poison at work in the etiology of a complex disease known for many years under the name of syphilis; and he who now recognizes a duality of poisons in venereal sores, is a syphilitic "dualist" in the sense in which that term has been employed. It will be seen, however, that the term "duality of syphilis" has always been a misnomer, and the form of the question presented to us to-day is most appropriately substituted for it.

I take it for granted that the question proposed to us is intended to include the poison or poisons of every kind productive of venereal ulcers, and that the term virus is to be used in its broadest sense, viz., that of *contagious principle* or *poison*. When speaking of a special poison supposed to be incapable of generation *de novo*, I shall call it a *specific virus*.

Allow me also to add that I shall use the terms *chancre* and *chancroid* in the sense which is commonly received in this country—chancre as indicating the initial lesion of syphilis, and chancroid as indicating the "soft chancre" of the French school, and the "chancre" of the German school.

Three views as to the origin of venereal sores have been entertained:—

(1) All venereal sores are due to a single, specific virus, the virus of syphilis.

(2) Some venereal sores are due to the syphilitic virus, and others to a distinct specific virus, known as the *chancroidal*.

(3) Some venereal sores are due to the syphilitic virus, and others to the inoculation of the products of simple inflammation, in which latter case no specific virus exists.

The clinical observations and artificial inoculations, which have been brought forward, for and against these several theories, must be familiar

to those here present, and I shall therefore limit myself to reviewing them and drawing my own inferences from them, as a basis for the discussion which is to follow. Indeed, any other course would be impracticable within the limits of this paper.

The view first mentioned, viz., that all venereal sores are due to a single virus, the virus of syphilis, had been the prevailing one for nearly three centuries prior to the year 1852. At the same time, it had not escaped the notice of many observers that the results of contagion were by no means identical; that, in some cases, the persons infected showed no symptoms after the healing of their ulcers, while others developed a train of symptoms, lasting through years, and even transmissible to their children.

In the year 1852, Bassereau claimed a distinct cause or origin for each of these two classes of cases. He founded his claim, first, on the history of venereal sores, whereby he endeavored to show that, although contagious ulcers of the genital organs, communicated in sexual intercourse, had been well known to the ancients, yet that the constitutional disease which we call syphilis made its first appearance in Europe in the latter part of the fifteenth century.

While believing this argument drawn from history to be a valid one, I would not insist upon it in a discussion like the present, which should be based upon scientific data. I will merely remark that this argument will receive additional support, provided that it can be shown that the chancroid is due to a poison generated by simple inflammation, and hence that it must have existed at all times and among all nations.

Bassereau's second argument was based upon the "confrontation" of persons affected with venereal diseases, and he and others were able to prove, in several hundred cases, that when the disease was local in the giver it was also local in the recipient, and that when it was constitutional in the giver it was always constitutional in the recipient; in other words, that the broad line of distinction separating a local disease on the one hand from a constitutional disease on the other, was constant in successive generations without limit.

It will be observed that this proof does not involve any differences real or supposed in venereal ulcers themselves; it may be said to rise above such consideration in that it ascends to the source and origin; and I do not hesitate to say that much of the confusion and contradiction of opinion upon this subject has been due to the fact that observers have confined themselves to investigating symptoms, which, though generally constant, may yet be poorly marked or even wanting, and which often require practised eyes and fingers for their recognition.

Now I maintain that this clinical proof adduced by Bassereau has never been shaken, for, although local ulcers have been produced by the inoculation of matter from syphilitic sores, yet this is susceptible of, and indeed requires, as we shall see hereafter, another explanation than an identity of poisons, and, on the other hand, *there has never been a single authentic case in which syphilis has been produced by the inoculation of chancroidal matter from a person who has had only a chancroid and not syphilis.*

Bassereau does not appear to have speculated on the cause of the difference in venereal ulcers. I do not find in his work the words "Unity or Duality of Syphilis," nor any expression of opinion as to the existence of a specific virus for the local sore. He simply says that he is obliged to recognize a different cause (*une cause différente*) for the local and constitutional diseases.

A school of dualists, however, soon sprang up, who departed from the simple faith of their founder in attaching undue importance to the characteristics of the sores themselves, and who claimed for the local sore a distinct, special virus of its own.

One of the tenets of this school was that the secretion of syphilitic lesions could not be inoculated with success either upon the person bearing them or upon any other person affected with syphilis, and this tenet, in the theory of dualism, was looked upon as vital.

It was not long, however, before it was successfully attacked and overthrown. Clerc, of Paris, Melchior Robert, of Marseilles, and others, succeeded in inoculating the secretion of syphilitic sores upon the bearers, with the result of producing ulcers, without incubation, bearing all the characteristics of the chancroid, and inoculable in successive generations. Mr. Henry Lee, of London, and Köbner and Pick, in Germany, also found that a true chancre would become auto-inoculable, if it was irritated by the application to its surface of powdered savine, or by having a seton passed through its base, so as to render its secretion decidedly purulent. Again, Boeck and Bidenkap, in Christiania, in their later attempts at syphilization, took matter exclusively from true chancres, and obtained the same result as when they had inoculated chancroidal pus. In five cases reported by Bidenkap and Gjör, of Christiania, matter was taken from ulcers obtained in the above manner, and inoculated by patients free from syphilis upon themselves, and in only one instance did any general symptoms ascribable to syphilis follow, and these were of a doubtful character.

Gentlemen, the import of these successful auto-inoculations of syphilitic lesions as regards the question before us, deserves our serious consideration. Let us inquire what they apparently proved, and what they actually did prove. They *apparently* proved the identity of the syphilitic poison with that of the local sore. By their means, it was supposed that the doctrine of duality was demolished, and the advocates of unity were triumphant. Whether this conclusion was not too hasty, we shall presently take occasion to inquire. But these experiments *actually did* prove the absence of any distinct *specific* virus in the chancroid, incapable of generation *de novo;* for here were chancroids artificially produced independently of any descent from chancroids.

You are well aware of the defence adopted by the dualistic school—the mixed chancre, a sore combining both the syphilitic and chancroidal specific poisons—which, it was asserted, would satisfactorily explain all these cases and still leave the tenets of dualism, as at that time understood, intact. This explanation was for a while regarded as satisfactory, but it could no longer be upheld when such experiments had been multiplied indefinitely; when their number was so great that the chances of the commingling of two kinds of specific virus and their simultaneous inoculation was reduced to a homœopathic absurdity; when an indurated syphilitic primary lesion could be taken at random, and, after due irritation, its secretion could be successfully inoculated with the effect of producing pustules and ulcers bearing every characteristic of the chancroid; and when the same result could even be obtained at will by the inoculation of the secretion from a purely secondary lesion, as, for instance, a syphilitic mucous patch! If the chancroid was dependent upon a distinct specific virus, its presence in all these cases was simply impossible, and yet not a single shade of difference could be pointed out between the result produced and that from the most emblematic chan-

croid ever met with in practice. Dualism was indeed henceforth demolished, if by "dualism" be meant that each of the two kinds of venereal sore has a distinct, specific virus of its own. In the face of the experiments referred to, I cannot believe it possible to defend in future any such doctrine of duality.

But the last word had not been spoken in favor of a distinct origin of the chancroid from that of syphilis, nor the last experiment made and recorded which would decide the question before us to-day. Let us examine more carefully those experiments I have just referred to. What was the matter so successfully inoculated? The pure, unmixed virus of syphilis? By no means. It was a compound product, taken, to be sure, from a syphilitic lesion, but a lesion irritated commonly to suppuration by artificial means; containing possibly the germ of syphilis, but containing also, and in fact chiefly composed of, *pus*. Which of these two factors was responsible for the effect produced? The syphilitic virus? In that case this virus should have preserved its power of infecting the constitution, and matter taken from these ulcers, and inoculated upon healthy individuals, should invariably have produced syphilis, which has been shown not to be true. Moreover, if it could be proved that pus alone, free from all suspicion of syphilitic mixture, was capable of producing the same result, then pus was the guilty factor, and there was no such transformation as supposed by the unitists. Such proof we now have as will be seen from the following cases:—

In 1865, Prof. Pick, at the suggestion of Prof. Zeissl, inoculated simple, non-venereal matter of inflammatory origin upon syphilitic subjects. Taking the secretion from pemphigus, acne, scabies, and lupus, he inoculated it upon persons affected with syphilis and produced pustules, not preceded by incubation, and the matter of which was further inoculable through several generations. Counter-inoculations upon the persons free from syphilis who were the bearers of these affections, were without effect. The same result was attained by Kraus and Reder with the pus of scabies, and by Henry Lee with pus from a non-syphilitic child. The late Mr. Morgan, of Dublin, also succeeded in producing pustules and ulcers, identical in appearance with the chancroid and capable of re-inoculation through a number of generations, by inoculating syphilitic women with their vaginal secretions.

It would thus appear that the skin of syphilitic individuals possesses a marked vulnerability, a peculiar aptitude to become inflamed when acted upon by irritants; but this is nothing more than is seen in other non-syphilitic subjects, whose vital powers are impaired by any cause whatever. For instance, it is well known that among medical students engaged in the dissecting-room, it is those who are run down by hard study and overwork, who are most likely to become inoculated by fluids from the dead body. Again, the idea which was entertained by some that there must be a syphilitic soil for such inoculations to succeed upon, is disproved by other experiments which I have to relate.

The earliest of these experiments, as far as I am aware, have never been published, and were performed in the winter of 1867–8 by Dr. Edward Wigglesworth, Jr., of Boston, upon himself, while pursuing his studies at Vienna. He has kindly furnished me with the following history: After stating the grounds which led him to the conclusion—original, it appears, with himself—that "*pus pure and simple might be the cause of the chancroid,*" Dr. W. says:—

"I would state that I was free from all disease either hereditary or acquired; that I had never had a sore of any kind or any local or constitutional lesion of the skin or mucous membranes, and that I was merely a little run down from overwork in the hospital. I took from an acne pustule upon myself, pus, which I inoculated upon myself in three places on the anterior radial aspect of my left forearm at the junction of the middle and upper thirds, first pricking open the apertures of hair follicles and then rubbing the pus into them. The result in the course of three or four days was three well-marked pustules. From each of these I inoculated one new spot upon the same arm nearer the wrist. The result was three new well-marked pustules. From each of the three of the second series I again inoculated fresh spots still nearer the wrist, and again the result was positive. The second series was hardly as well-marked as the first, and the third series was slightly inferior in vigor to the second; still all were well marked, the nine sores being at the same time present upon my arm. On removal of the crusts, perceptible ulceration of the skin was found to exist. Zeissl, with whom I was studying at the time (1867–8), happened to be lecturing upon dualism, and requested me to show my arm to the class to prove the production of ulceration from properly inoculated, simple, healthy pus. There were no buboes in my case, nor did the ulcerations require other treatment than exclusion from the air by means of a simple dressing, and cleanliness. The scars remain to the present day. I thus convinced myself and others—

"I. That the products of inflammatory action, if properly introduced into the human integument, may cause local ulcers, closely resembling chancroids and re-inoculable in generations.

"II. That this pus need not come from a syphilitic person or be inoculated upon a syphilitic person. If taken from, or inoculated upon, a person debilitated by any disease as syphilis, the effect would doubtless be the same though probably greater in intensity."

Many years subsequent to these experiments of Dr. Wigglesworth, which ought to have been made public at a much earlier date, Kaposi[1] published the following statement: "My own experiments have taught me that non-specific pus, such as that from acne and scabies-pustules, when inoculated upon the bearers as well as upon other non-syphilitic persons, will produce pustules whose pus proves to be continuously inoculable in generations; that from these pustules losses of substance occur, which heal with the formation of scar-tissue; and that as the number of pustules produced increases, the inoculability of the pus derived from them diminishes and finally ceases altogether."

It is not necessary for me to dwell upon the exact correspondence of the result of such inoculations and that obtained by the inoculation of so-called chancroidal matter.

The idea that the products of inflammation are the source from which the chancroid springs, and that the simultaneous inoculation of these products and of the germs of syphilis will account for the varying degrees of ulcerative and other phenomena met with in varieties of venereal sores, will strike many of you as novel, and it is easy to foresee the objections which will naturally arise. It will be asked: Can it be possible that the pus from acne, ecthyma, or scabies can give rise to a sore equal in duration and severity to that produced by matter from a typical chancroid? Comparative inoculations upon the same individual with these two agents may even be adduced to show that this is not the case. In replying to such objections, it must be frankly admitted that we do not as yet fully understand all the laws governing the inoculation

[1] Die Syphilis der Haut, etc., p. 47.

of septic matter. We cannot, for instance, fully explain why one individual should be more susceptible than another, why different parts of the integument, as that of the chest, the arms and the thighs, should develop ulcers so varying in their destructive tendency as is shown in the practice of syphilization; why the secretion from purulent urethritis and purulent conjunctivitis should be interchangeable, and yet have no effect upon the mucous membranes of the mouth, nose, or ear; why a chancroid of the prepuce should inoculate other points of that membrane, and yet commonly spare the glans penis; or why one upon the os uteri should allow the walls of the vagina in contact with it to escape; and so with other instances that might be brought forward.

That the effect produced is to a great extent proportionate to the ulcerative action of the source from which the matter is taken, is evident to any one who has performed auto-inoculation from indurated chancres. If the chancre consist of a simple erosion with a watery secretion, seated upon an indurated base, the first two or three, or even more, attempts at auto-inoculation will probably fail; but as the surface of the sore becomes irritated to suppuration by repeated pricks of the lancet, these attempts will succeed, first in producing minute pustules and ulcers, but subsequently, as the suppuration increases, others larger and better developed. Taking these facts into consideration, it need not be wondered at if comparative inoculations upon the same individual with matter from a simple skin affection and from a chancroid of the genitals, should show greater severity in the latter. But without entering further into this subject, I claim it to be sufficient to have shown that the inoculation of the products of inflammation will produce an effect identical *in kind*, even if not in degree, with that of matter from the most typical chancroid; and this is my reply to the objections I have named.

I have now, gentlemen, called your attention to the evidence drawn from artificial inoculation in favor of a duality in the poison of venereal sores, some of them being derived from the virus of syphilis, while others are due to the products of simple inflammation. This view, which I believe to be most consistent with our present knowledge of pathology, and to be supported both by experience and scientific investigation, has of late years found its advocates among medical men.

Thus Bäumler, in his recent able work on syphilis, after quoting experimental inoculations like those just given, says:—"The necessary conclusion is, that the *poison of the soft chancre may, under certain circumstances, be produced de novo without the intervention of the syphilitic virus,* while the syphilitic poison propagates itself only in one continuous series. Hence the chancroidal poison, or whatever in these experiments produced the pustules resembling chancroids, cannot even be compared with the syphilitic poison, to say nothing of regarding them as identical."

In the recent and well-known debate upon syphilis before the Pathological Society of London, that accomplished surgeon, Mr. Hutchinson, came within one short step of the truth when he admitted the origin of the local venereal sore to be "the products of syphilitic inflammation, but not usually containing the germs of syphilis." If he had omitted the adjective, "syphilitic," before the word "inflammation," his expression would have been consistent with the facts at present in our possession, and he would have found it inconsistent with such facts to proclaim

dualism as dead, since, as I have already shown, dualism is nothing more than a duality of poisons in the evolution of venereal sores.

If the view which I advocate be the correct one, it suggests an interesting analogy with the history of our belief as regards the nature of gonorrhœa, an affection which in the last century was regarded as due to the syphilitic virus. Ricord finally adduced convincing proof that it had nothing to do with syphilis. It was afterwards supposed to depend upon a virus of its own, the gonorrheal virus. We now know that it may be caused by any simple irritant, but more especially by the pus from the urethral and other inflamed mucous membranes, whether originating or not in contagion. Such as the history of gonorrhœa has been, so, I predict, the history of the chancroid will be.

In the preceding remarks, I have only casually alluded to the evidence in favor of a duality of poisons to be found in the symptoms presented by venereal sores themselves, and by the lymphatic ganglia in anatomical relation with them. The value of this evidence must always depend upon the observer's knowledge, skill, and experience in venereal diseases. How often do we witness the grossest errors in the diagnosis of venereal ulcers made by men who are deservedly eminent in general practice? Moreover, instances not unfrequently occur in which the symptoms are ill-defined, and in which the most experienced will wait for further developments before expressing an opinion. Hence, so long as the symptoms of the sores themselves were alone considered, the question of unity or duality remained undecided. And yet, to my own mind, the evidence founded on these symptoms is not to be despised, for in the great majority of cases they are sufficient to enable us to distinguish the syphilitic from the local sore, and the obscurity of some cases is readily explicable on the ground of the simultaneous inoculation of the products of inflammation and the germs of syphilis, and the well-known immediate action of the one and the incubation of the other.

One word as to the form of the question with which we started out. It may appear to some that as the products of inflammation are various, the question should read thus: "The virus of venereal sores, its unity or plurality?" But this is a matter of small moment. If any one prefers the latter reading, I have no doubt it will be accepted as an amendment. The actual point at issue is whether the syphilitic virus is, or is not, responsible for all the venereal ulcers met with in practice, and this is sufficiently implied in the question as originally worded.

Gentlemen, I will not longer detain you. I must apologize for the incompleteness and brevity of my remarks, necessitated, however, by the short time at our disposal.

The conclusion which I have to offer you, is based, as I have endeavored to show,

(1) Upon clinical experience, more especially in the confrontation of persons affected with venereal sores.

(2) Upon artificial inoculation.

(3) Upon the corroborative evidence presented by the symptoms of the sores themselves.

For convenience of discussion I shall divide my conclusion into the following propositions:—

I. The virus of venereal sores is dual.

II. Some venereal sores are due to the inoculation of the syphilitic virus.

III. Other venereal sores are due to the inoculation of the products of simple inflammation.

IV. These two poisons may be inoculated simultaneously.

Discussion on Dr. Bumstead's Paper.

After the reading of the preceding paper, Dr. R. W. Taylor, of New York, said:—The Section is to be congratulated upon having presented to it such an exceptionally perfect paper as that read by Dr. Bumstead; it is certainly the best exposition of the subject which I have ever listened to or read in any language. And I am glad to be able to say that my experience coincides with the observations of the distinguished writer. As bearing upon the distinction between the virulence of the pus of a chancroid and that of an initial syphilitic sore, I may refer to a case observed by myself of a man who in the first year of syphilis contracted gonorrhœa, and, having a long, tight prepuce, suffered from herpetic vesicles, which assumed the character of chancroids; buboes formed in the groins, and the pus from these ran down the thighs and produced pustules, which were healed with great difficulty. The man's wife was not then, nor is she at the present time, syphilitic, but she too suffered from chancroids. Another case was that of a newsboy whom I saw at a dispensary in New York; the boy was not in any degree syphilitic, and was believed to have been up to that time virtuous, but was suffering from a bad sore upon his leg; the pus ran down and produced ulcers similar to chancroids; this boy by sexual intercourse subsequently contracted syphilis.

Dr. E. L. Keyes, of New York, said:—Dr. Bumstead's third proposition presents the true question at issue. No doubt pus from simple inflammations may produce ulcers upon persons in a condition to be easily impressed, but such ulcers are not identical with chancroids. Pus is, of course, irritating, and different kinds of pus have different effects; but I do not think it proved that simple pus applied to a healthy person will produce anything identical with chancroid. The paper just read does not describe the ulcers said to have been produced by simple pus, and I do not think that it has been shown that they were typical chancroids. Urethritis is quite common among married persons, and so are excoriations among persons with tight prepuces; some persons even cannot have sexual intercourse without producing herpetic vesicles, but the resulting ulcers are not chancroidal. To say that ulcers from simple pus are identical with chancroids, is going too far. If that were the case, every one would be in imminent peril of becoming sooner or later a victim to this affection. In a majority of cases, the pus of acne will not produce upon a healthy person an ulcer identical with chancroid.

Dr. Bumstead said:—The time allowed for the reading of my paper excluded a description of the sores mentioned in it; and I thought it sufficient to state that Kaposi had been unable to discover any difference between chancroids and the sores thus produced. I have said in the paper that the more healthy the person, the less liable will he be to the evolution of the sores.

Dr. Keyes said:—I would ask Dr. Taylor when the chancroidal ulcers appeared in the case which he has described?

Dr. Taylor said:—I took very full notes of the case, but have them not with me; I can say, however, that the herpetic vesicles appeared about the tenth day after exposure, and that they assumed the chancroidal appearance about the twelfth or thirteenth day.

Dr. D. R. Porter, of Kansas City, said:—I am a believer in dualism, but I cannot believe that a chancroid can be produced from an inflammation not chancroidal; nor do I see how it is possible for herpetic vesicles to turn to chancroidal ulcers. I believe that chancroids are different from syphilis, and that chancroids are always developed before the tenth day.

Dr. Bumstead said:—Chancroids are always developed before the tenth day, and the only way in which the development can be deferred is for the virus to lie upon the surface some days without being taken into the tissues.

Dr. Taylor said:—There was no possibility of that in the case which I have mentioned, for the patient washed the penis in warm water frequently, and the continual wiping of the gonorrhœal discharge would have been sufficient to remove the virus from the surface.

Dr. Keyes said:—It is impossible for me to believe that a chancroid could appear as late as eleven days after exposure.

Dr. L. D. Bulkley, of New York, said:—I do not believe that the weight of evidence sustains the proposition, and I believe that the chancroid has no connection with syphilis.

Dr. Charles Heitzmann, of New York, said:—There are some persons very liable to pustules, and upon whom small lesions will produce them. During many years that was my own condition. I have witnessed many experiments in Vienna, but have seen no evidence of the analogy between the sore produced by simple pus and chancroid.

On motion, the propositions appended to Dr. Bumstead's paper were adopted as expressing the opinion of the Section, with the exception of the third, for which, on motion of Dr. Bulkley, the following was substituted:—"Science has demonstrated that suppurative inflammatory lesions, which resemble in certain features what we know as chancroids, may be produced on various parts of the body by inoculation with simple pus from various lesions."

LEPROSY AS OBSERVED IN THE SANDWICH ISLANDS.

BY

FRANK H. ENDERS, M.D.,

GOVERNMENT PHYSICIAN.

[COMMUNICATED BY THE SECRETARY.]

THE history of leprosy as it exists on these Islands is yet very obscure. Its advent or origin cannot be traced with any degree of satisfaction. Among the present generation it is known as *mai-pake* (Chinese sickness), they contending that the first case ever known here was in a Chinaman. The older class of natives formerly knew it under the name of *mai-alii* (sickness of chiefs), and describe the disease as it existed then, precisely as we find it here at the present time. Some of the older foreigners, who have resided here for many years, and before the importation of the Chinese, recognize the present disease, or one closely resembling it, as having existed here as far back as the year 1830. If this be true, it is certain not to have been brought here by the Chinese.

The question of importance yet to be solved is, whether it is a disease *sui generis*, or a form of syphilis peculiar to the climate and dependent, to at least some extent, upon the habits and diet of the people.

It is no easy matter to arrive at a positive conclusion, for there is reasonably strong evidence advanced for the support of both theories. Since my residence upon the Islands, I have examined over four hundred cases of the so-called leprosy, and I am as yet unable to determine which of the two positions is the more tenable, or which view rests upon the stronger evidence. One great trouble or difficulty rests in the fact that almost every native either has, or has had, syphilis, acquired or inherited. Of the large number examined, I have found but two in whom there could be any doubt as to the pre-existence of syphilis, and in these two exceptions close relationship could be traced to persons having leprosy.

Two forms or varieties of the disease are observed, viz.:—the anæsthetic and the tubercular. At the present writing, there is sitting in my office a native woman about twenty years of age, married and having two children, one six and the other three years old. She is of medium height, weighs 146 pounds, and, to a casual observer, is a picture of health. Scrutinizing her more closely, we detect two brownish spots, one upon either cheek, which, to an experienced eye, tell only too plainly the terrible fate that awaits her. Her left arm hangs cold and lifeless at her side; this condition, she says, began about one year ago, with a numbness in her fingers, which lasted for a few weeks, since which time there has been an entire loss of sensation from the elbow downwards. In her case there is not only cutaneous anæsthesia, but a needle can be thrust through the skin, superficial fascia, sheath, and muscle itself, without giving rise to the least pain. The extensor and flexor muscles are relaxed, and can only be slightly contracted or extended. The ligaments are very elastic, permitting the fingers to be laid quite back upon the dorsum of the hand. The skin of the affected

arm is dry, harsh, and flabby, all of the fatty matter has disappeared, and the muscles are also atrophied. There is slight anæsthesia along the course of the gastrocnemius muscle of the left leg. This patient has had syphilis. There is no indication as yet of the existence of the disease in her children. She disavows having been associated in any way with a leper.

In the tubercular form of the disease, the earliest indications observed of its approach are tubercles upon the base of the tongue, falling off of the eyebrows, and a thick, corrugated state of the skin upon the forehead and cheeks. The ears become thickened, the helix being enlarged and the lobe at times as large as a hen's egg. Ectropion is often found in the incipient stages. Frequently the existence of these early indications after a few weeks or months is followed by ulceration. The fingers and toes drop off, this condition being accompanied by great distortion. In some cases the bones of the fingers and toes become absorbed, except small portions of the metacarpal and metatarsal bones, upon which the nails remain intact. There is more or less insensibility of the skin, but not so marked as in the other form of the disease. When ulceration of the nasal mucous membrane takes place, the sense of smell is lost, the vomer is absorbed, and considerable deformity of the nose results.

The present superintendent of the leper asylum, W. P. Ragsdale, a half white whose father was a Virginian, is a very sensible, educated man. He says that the first indication of leprosy apparent in his case was an ulcer on the bottom of his foot which could not be healed. He supposed this to be the result of syphilis, and so believed until the contraction of the flexor muscles, and the thickening of the skin on his forehead and cheeks, occurred, when he recognized himself to be a leper.

Another frequent accompaniment of this disease in its tubercular form is keloid tumor; in fact, by some physicians this is considered as pathognomonic of the disease. Cataract is often found in both forms of leprosy. There can be little doubt that the two forms are varieties of one common morbid condition. I have seen but two cases of elephantiasis Arabum (Barbadoes leg), one in a native, the other from the island of Tahiti.

Leprosy does not appear to be more frequent in one sex than in the other, but it is often the case in women that as long as the menstrual function remains perfect, the disease seems to be kept in abeyance. The least disturbance or irregularity of menstruation which occurs, causes a rapid progress in the disease. Conditions of society seem to have little effect, the disease attacking high and low of native race. The disease is confined almost exclusively to the native population. I have observed fifteen cases among Mongolians and four among Europeans, the latter being males of the lower order, living entirely with the natives, eating *poi* and salt fish, and sleeping in overcrowded filthy huts. Each of these white men presented undeniable evidence of the pre-existence of syphilis.

The disease is not confined to any locality, or elevation, but where prostitution is most rife, there the most cases will be found. I believe the disease to be hereditary, and in illustration of this fact I will give the following cases which are well substantiated:—

A native woman on this Island bore five children by a leprous husband; the disease was developed in each of these children, between the ages of eight and twelve years, and they were taken to the Leper Asylum where they have since died. The husband died from the same disease. The woman afterwards married a healthy man, and has now three children past the ages at which the

disease occurred in the other set. They are stout, healthy youngsters, with no indication of the disease in their systems.

A few weeks since the police brought to me a leprons woman, the mother of four children, the eldest eight years of age, the youngest two months. She was far advanced in the disease, her body covered with foul ulcers, with loss of phalanges of one hand, corrugated skin, and ectropion, and she was suckling the infant, which, together with the two next older children, was apparently in good health. The eldest, a boy, bore evident signs of the existence of the disease, having tubercles upon his tongue, ectropion, a bronzed appearance of the skin, with slight thickening. As a rule, leprous women are sterile, but in this case we find the contrary, although she had had the disease, according to her own statement, for thirteen years.

I am strongly inclined to the belief that leprosy is not a disease *sui generis* but an offspring of syphilis, although from New Brunswick, Bermuda, Jamaica, Dominica, Guiana, Cape of Good Hope, and some other countries, come reports to the contrary. I am compelled to believe as I do until stronger evidence is offered by these writers for the support of their theory. Dr. Stephenson, from Barbadoes, says:—I will not say that syphilis can produce true leprosy, but it is more common in the offspring of syphilitic parents. Dr. Hende, in his report from Magpore, in India, ascribes a portion of the cases to syphilis. Drs. Reed and Pollard, from Guiana, deny any connection between leprosy and syphilis, while Dr. Van Holsh, from the same place, says, "I believe leprosy to be connected with syphilis, yea, to be the offspring of it." Dr Trousseau, of Honolulu, says, "I believe that in syphilitic patients there is a predisposition to leprosy." Dr. McRobbin, a member of the Board of Health in Honolulu, says, "I believe leprosy to be an offspring of syphilis." The two last-mentioned gentlemen have had large experience in this disease, and so strong is their belief in its relationship to syphilis that they have stated that the eradication of syphilis from these Islands, would eventually cause the disappearance of leprosy, or, according to the number of cases of syphilis allowed to run its course, through its different stages, in such proportion will exist the number of cases of leprosy. Here again, on account of the widespread existence of syphilis, it is impossible to ascertain the extent of the contagiousness of leprosy, if it be contagious.

In the general acceptation of the word, by indirect contact, none of the medical men on these Islands believe it to be so; as to direct contact, there seems to be some doubt. The woman already referred to, who bore five children by the leprous husband, still lives, and bears no signs or symptoms of the disease. The wife of the present superintendent of the lepers has had three leprous husbands, and now lives, and has lived for many years, at the asylum, and yet bears no evidence of the disease. Père Damien, a Prussian priest, and a most excellent man, has devoted his life, during the last few years, to the welfare of these people, living the same secluded life, ministering to them in sickness and in health, working with and associating with them; yet the blighting curse has passed him by, and left him as yet unscathed.

Many cases might be noted to sustain the view of the non-contagiousness of the disease, yet I am strongly inclined to the belief that it is oftentimes conveyed by direct contact, through sexual intercourse or inoculation in other ways; several instances have been known, on these Islands, of women who have married second and third husbands, after the death of the first from leprosy, their later husbands sharing the same

fate as the first. Whole families, and those intimately connected or associated with them, have thus become diseased.

The natives seem to have no fear of the foul pestilence, and can often be found huddled together, men, women, and children, sick and well, under the same covering; smoking the same pipe which comes poisoned from the secretions of the leper's mouth; eating from the same *calabash*, when the hands and fingers are covered with ulcers. Dr. Manget, writing from Guiana, says: "I have met with only two cases in which, after minute inquiry, I believed the disease to have been communicated by direct contact." Dr. Regnaud, of the Island of Mauritius, says: "I have met with two instances in which the disease seemed to have been transmissible, in one instance from the husband to his wife, and in the other from a man to a child of his wife by a former husband." Drs. Pollard and Van Holsh, of Dutch Guiana, assert positively that it is contagious. From Ceylon, Bombay, Madras, Bengal, Calcutta, Magpore, and Benares, comes the report that it is not contagious.

A few years since, when smallpox was epidemic upon these Islands, vaccination became promiscuous. Shortly afterwards, leprosy was largely on the increase, and by many it was ascribed to this cause. The then Minister of the Interior (a graduate of medicine, too), appointed laymen to travel over the country and "vaccinate everybody." The subjects from whom the virus was taken were natives; it was transferred from arm to arm; and if leprosy is contagious, as this gentleman himself asserted in reports to the Legislature in 1872, the people of this country can, to a great extent, lay at his door the cause of the increase. In 1870, a law, similar to the "social evil law," in St. Louis, was enacted here by the Legislature, and put in full force; Dr. McRobbin, upon whom devolved the duties of Medical Officer, with his usual zeal and earnestness, went to work and accomplished much good; but this law was doomed to the same fate as that in St. Louis, and was repealed in 1872, the same idea of "licensing prostitution," as it was termed, prevailing here as there. That much good resulted, no one unbiassed by prejudice can fail to see, and had the law continued in full force to the present time, its effects would have been plainly visible, without the necessity for statistics to tell us of the good accomplished.

The Leper Segregation, or Asylum, is located upon the Island of Molokai, where all lepers are confined. The asylum comprises about eight square miles. It is a low plain surrounded on three sides by the ocean, which expends its mighty force upon this land, unbroken by reef or shallow water. It is with great difficulty that a landing can be accomplished, and then only by the aid of experienced natives. Upon the remaining side rises the lofty *pali* or precipice of Kalanpapa, 2000 feet high. In the side of this *pali* is cut a narrow path by which the asylum proper is reached. It is a serious undertaking, to go down and return, as it must be done on foot, and a false step might land one more quickly at the bottom than would be agreeable. Having accomplished the descent in a quiet way, we find ourselves upon the flat or landing place, where there are a number of native huts, occupied by lepers; here we mount our horses and ride to the superintendent's house, about one and a half miles away. From this place we have a splendid view of the ocean, the *pali*, and the asylum. It is a grandly beautiful sight; one well worth the fatigue and dangers of the trip. The asylum is composed of 200 houses, in which live the lepers, alone, or with their families and friends. Directly in front of us is the hospital, built of wood,

and in a quadrangular form; in this building are to be found the more advanced cases of those not able to care for themselves; nurses are furnished, and they are well cared and provided for. There are 696 inmates in the whole segregation; their houses are clean and neatly kept; food, both in quantity and quality, all that they can wish. The establishment is well regulated and governed; it is controlled by the Board of Health, and its present condition is greatly due to the energy and zeal of the Hon. S. G. Wilder, President of the Board. The number of cases of leprosy now at large upon the Island is very small, and the disease is evidently upon the decrease; and this decrease is, in my opinion, due to the improvement in the number of cases of syphilis, brought about by the Government and Board of Health, which furnish all natives with medical attendance and medicines free of charge, and in this way induce them to leave their old superstitions and harmful methods of treatment by *Kolumas*, or native doctors. Since 1866, no less than 1570 lepers have been received into the asylum, while 872 have died, leaving, at the present writing, 698 inmates.

In an affection so grave, we can but feel how limited is our knowledge, and how far beyond the resources of our art is this blighting curse. Still, we may be able to do something, not to relieve pain—for the sufferers usually pass through the several stages of the disease with but little pain and suffering—but to stay the progress of the malady, and to afford relief in intercurrent affections to which the debilitated condition of the patients renders them peculiarly liable; as, for instance, pneumonia, hepatitis, erysipelas phlegmonodes, conjunctivitis, etc.

The remedies which I have found most valuable in the incipient stages of leprosy, are more particularly the protiodide of mercury, given in doses of one grain daily, with half a grain of opium, and pushed to slight ptyalism; afterwards the liquor potassii arsenitis, twenty drops daily, continued for some days, when, if circumstances are favorable, the corrugations of the skin disappear, the eyes assume a better color, and a vast improvement in the general appearance of the patient is observed. This improvement may continue for weeks or months, when suddenly, without any apparent cause except perhaps inclemency of weather, the disease returns, and in all probability in an exaggerated form. In the more debilitated cases, the tinctura ferri chloridi is given with benefit. Drs. Donaldson and Boeck have found the internal use of mercury injurious in leprosy, but, given as before stated, I have found no evil results to follow; on the contrary, at least a partial control of the rapid progress of the disease has attended this treatment in my hands.

As an external remedy, I make use of the ointment of the iodide of sulphur, applied after washing thoroughly with warm water and carbolic soap. In some cases, the itching of the entire surface of the body is very severe, so severe, indeed, that the sufferers will, in their agony, tear out pieces of flesh with their nails; in this condition, I find the best application to be carbolic acid in the form of ointment, one part to four, which generally gives relief.

Discussion on Dr. Enders's Paper.

After the reading of the preceding paper, Dr. L. A. Duhring, of Philadelphia, said:—The paper is one of great interest, as it presents the question of a relation between leprosy and syphilis, which has never yet been satisfactorily

answered. My own opinion is that there is no relation between the two diseases. There is much division on the subject among those who reside in countries where leprosy prevails. From the remarks in the paper, and from my own observation, I would say that syphilis exists to a large extent in the Sandwich Islands, and that many cases there classed as leprosy are complications of the two.

The President, Dr. J. C. WHITE, of Boston, said:—The facts presented in the paper are interesting, and many of them are novel to me. I know that syphilis has for many years found a stronghold in the Sandwich Islands, and that leprosy, recently introduced there, has spread most rapidly. The suggestion of Dr. Enders concerning vaccination is valuable, as bearing upon the question of contagion in leprosy.

ON THE TREATMENT OF SEBORRHŒA.

BY

C. HEITZMANN, M.D.,

OF NEW YORK CITY.

SEBORRHŒA, in the definition of Hebra, "consists in a morbid secretion of epidermis, which is impregnated with sebum, and either forms a greasy coating or accumulates in scale-like masses upon a part of the skin which is, in other respects, healthy."[1] This disease, so very common on the scalp, where it bears the popular name of "dandruff," and on the face, especially on the nose, is, as dermatologists know, a very obstinate one, and difficult to cure. It is easy to remove the accumulated, fatty, epidermic masses, by rich applications of fat, by repeated washing with water and soap, and by repeated shower-baths; but a real and permanent cure can rarely be obtained by these means, even in those cases which are in intimate connection with diseases of the womb, or with a general trouble known as chlorosis, after the removal of such a primary or general disease. A short time after the treatment, the fatty scales return, the sebaceous masses gather again on the scalp and on the nose, and the disease runs its course, leading, after many years' standing, to atrophy of the sebaceous glands and the root-sheaths of the hairs, and at last to complete baldness. The latter result is very common with seborrhœa of the scalp, and was known to Hippocrates. Besides, the skin affected by seborrhœa is very liable to eczematous eruptions, especially when continuously scratched on account of an itching sensation commonly produced by an increased perspiration in summer time, or after excitement of the organism. If the disease be present on the face, repeated applications of irritating agencies, especially of the alcoholic solution of green soap, as recommended by some dermatologists, almost inevitably lead to a chronic dermatitis with induration and stiffness of the skin, a condition which gives a singular aspect to persons who have suffered a long time from seborrhœa of the face. If the disease be established on the nose, the chronic inflammation very often leads to enlargement of the bloodvessels, and the disease known as acne rosacea. Persons who have suffered in their youth from seborrhœa of this part, by and by acquire an enlarged, red nose, and in my experience are very liable to deforming eruptions of acne rosacea, the more, of course, if alcoholic drinks be taken, even in moderate quantities.

In the beginning of 1875, I was accidentally led to the local application of a remedy, which, as far as I can say after a relatively short experience, is capable of removing the disease radically. This remedy is tar. In a case of chronic squamous eczema of the scalp, apparently the result of seborrhœa, and complicated with a highly advanced baldness of the part, I applied the tar tincture, and not only cured the eczema but produced a new growth of hair, leading to a complete restoration of the

[1] On Diseases of the Skin, by Ferd. Hebra, M.D.; Edition of the New Sydenham Society of London, vol. i., 1866, page 104.

normal state. After a treatment of about two months' duration, the patient was cured, and remains cured and full-haired up to the present time.

The tar has been applied in seborrhœa of the scalp by Hebra, but only with the intention of removing the almost intolerable itching sensation by which the disease is sometimes accompanied. Furthermore, it has been applied in the form of tar ointment by Piffard, of New York, but only for a couple of weeks, alternately with different other remedies. Among the varieties of tar, I give the preference to the oleum rusci crudum, a product of dry distillation of the white birch. It is preferable to other kinds, as the oil of cade and the oleum fagi, on account of its relatively less offensive smell, this resembling the smell of Russia leather. Genuine ol. rusci is very slightly soluble in fatty oil, but readily soluble in alcohol. In private practice it is almost impossible to apply a fatty oil, as, for instance, the linseed or almond oil, impregnated with ol. rusci to the highest possible degree, because the smell of such a preparation is too strong, and to many persons intolerable. The alcoholic solution of ol. rusci, the so-called tar tincture, again, is rejected by most of the patients, because it blackens the scalp and renders the patient incapable of transacting business with other persons. The form which I have chosen, after different experiments, is that of a pomatum, in which the smell of the oleum rusci is killed by ol. rosæ, the only fragrant oil capable of covering the smell of tar to a satisfactory degree.

The formula which I have employed since March, 1875, is the following:—

℞. Olei rusci crudi, ℥ss;
Ung. aquæ rosæ, ℥iv;
Olei rosæ, gtt. x–xx.—M.

The quantity of rose oil to be added depends somewhat on the wealth of the patient, as it is a very expensive substance. In summer time we may unite melted wax or paraffin with equal parts of cold cream, in order to make the pomatum more consistent. The greatest care should be taken, on the part of the druggist, to mix the preparations named, exactly, and for a long time, inasmuch as the smell of tar is the less noticeable, the more carefully the union has been effected by mechanical means. Every evening, before going to bed, the patient rubs into his scalp, and not into his hair only, a quantity about the size of a small walnut; after that he has to cover his head with a tight, flannel nightcap, in order to press the ointment somewhat into the skin, and to avoid soiling the bed-linen. In summer time, as the wearing of a nightcap is unpleasant, it may suffice to protect the pillow with a suitable cover. Next morning the remains of the pomatum have to be taken off with a dry linen cloth, and then the patient may apply some fragrant pomatum. Twice a week he should take a cold shower-bath of moderate force, and about two feet in height, and as often should simply wash the scalp with water and Castile soap. Nothing further is necessary, and especially no internal treatment whatever is required.

The way in which the tar pomatum acts, is that after fourteen days the falling off of the hair is stopped; in fourteen days more the seborrhœa is gone; and again, fourteen days later, a distinct new growth of hair can be observed. After at least six weeks' treatment, the disease is in many instances cured. Slight relapses may occur, and are readily dealt with by repeated applications of the tar pomatum of much shorter

duration. In two cases of highly advanced baldness, evidently produced by former seborrhœa, and of several years' standing, I succeeded in producing a remarkable new growth of hair by the application of the above-named pomatum for two or three months. In cases of seborrhœa of the face, the continuous application of the tar pomatum, for six or eight weeks, will cure the disease and remove the stiffness of the skin. In cases of seborrhœa of the nose, besides greasing with the pomatum, repeated emptying of the enlarged sebaceous glands by mild squeezing with the finger-nails is enough to cure the disease even in chlorotic girls. As my experience embraces only twenty-eight cases of seborrhœa, though all were treated successfully in the manner described, I do not consider the value of the remedy as being thoroughly established. I bring the method before the profession in order to enable every physician to try such a simple treatment, and shall be glad to learn the results obtained by others.

THE TREATMENT OF SYPHILIS,

WITH

SPECIAL REFERENCE TO THE CONSTITUTIONAL REMEDIES APPROPRIATE TO ITS VARIOUS STAGES, THE DURATION OF THEIR USE, AND THE QUESTION OF THEIR CONTINUOUS OR INTERMITTENT EMPLOYMENT.

BY

EDWARD L. KEYES, M.D.,

PROFESSOR OF DERMATOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

I. Does a mild beginning in syphilis necessarily indicate that the malady will run a mild course, so that the duration of treatment may be regulated thereby?
II. Is the internal use of mercury debilitating?
III. When is mercury useful in syphilis? Has it any control over the late symptoms?
IV. When is iodine useful in syphilis? Can it replace mercury in any stage of the disease?
V. Does iodine act by liberating mercury lying latent in the tissues?
VI. Should treatment be continuous or interrupted?
VII. General outline of a course of internal treatment.
VIII. Conclusions, negative and positive.

I. *Does a mild beginning in syphilis necessarily indicate that the malady will run a mild course so that the duration of treatment may be regulated thereby?*—My subject restricts me to the constitutional remedies appropriate to the different stages of syphilis, and I shall keep as closely within the prescribed limits as the nature of the question will allow. It is necessary, however, to answer this first proposition before taking up the general consideration of constitutional treatment.

I need not cite authorities to prove that syphilis, commencing mildly, is often looked upon as a trivial, self-limited disease. Such a belief prevails in the minds of many physicians to-day. It has received the sanction of high authority. Diday,[1] of Lyons, has taught it boldly for many years, and Lancereaux in the main supports his views. Diday divides syphilitic patients into two classes. Of these, one class, embracing about two-thirds of the whole number, says Diday,[2] contains cases beginning mildly. The prognosis in these cases is declared to be good; the patients are treated mainly by expectation; and mercury is considered unnecessary and even harmful. Cases commencing severely, the other class, get mercury; but, so the teaching goes, they only get it as an evil less bad than the severe syphilis which it is used to counteract, and the obvious conclusion is that the remedy must be employed during only a

[1] Histoire naturelle de la Syphilis; Paris, 1863.
[2] Diday et Doyon, Thérapeutique des Maladies vénériennes et des Maladies cutanées; Paris, 1876, p. 254.

short time to overcome the symptoms, and must not be continued to the injury of the patient. Lancereaux[1] is particularly strong on this point, and I think that a similar conviction is widespread among the profession in this country, the general notion being that mercury is bad, and only to be used because syphilis is worse. And even if this were not so, and if the profession should become a unit in regarding any given case of syphilis as liable to prove serious in the end, yet it would still be impossible to subject all cases commencing lightly to prolonged treatment. The ordinary patient can neither convince himself, nor be convinced—after his first alarm is over, and his trivial early eruption past—that he is likely to suffer severely from his disease at some indefinite, future period, and in the conviction that he will not so suffer, his physician is very apt to encourage him.

It is certainly true that most cases of syphilis commencing mildly continue to preserve their mild type whether treated or not, and are not so apt to lead to serious later troubles as where the earlier lesions are bad, the chancre, perhaps, phagedenic, and the first eruption pustular. It is natural that this should be so. Phagedæna is a personal peculiarity, and not a syphilitic symptom, and it is fair to assume that the quality of constitution which allows phagedæna to occur in a given chancre, will also cause the symptoms which follow it to be proportionally severe. It is the same with a tendency to form pus on light provocation, either in the elimination of an internal poison, or from external cause; this pyogenic tendency is a personal matter and by no means a symptom of syphilis, and where it shows itself in the early outbreaks of the disease by a pustular or even by a vesicular eruption, it is only natural that the course of the future symptoms should prove severe.

That these qualities of phagedæna, pustulation, etc., are personal, and not due to the acquisition of any especially bad type of disease, I think is easily demonstrable. I have seen more than once two patients whose syphilis had been derived from the same source, run a widely different course in their symptoms. The fact seems to me to be that an individual shows himself up physically when he is prostrated by the first onset of syphilis. A light beginning in the disease seems to indicate that the patient has power to rally and make a good fight. The physician, therefore, lulls himself into a belief that the patient can manage his disease without much aid from medicine, and, as the remedy, mercury, is regarded as an evil, he concludes that the patient is best off with as little of it as possible.

This reasoning would be unimpeachable were the premises accurate, but they are not so. First, mercury is not an evil. It is not debilitating, but tonic, in health as well as in disease, when continuously used in minute doses. This I think can be proved, and, if so, it becomes obvious that even if only a small percentage of the mild cases of syphilis become severe after a lapse of years, it is justifiable to submit all cases to such a continuous treatment as, itself tonic and beneficial to the patient, shall prove capable of keeping down symptoms during its use and for a considerable period afterward. Second, no one can tell how many cases commencing mildly may become severe in the end. That very many do

[1] Traité de la Syphilis; Paris, 1874, p. 548. "Un certain nombre de spécialistes, etc. . . . se croient obligés d'administrer le mercure pendant plusieurs mois, quelquefois même pendent des années; . . . . loin de s'opposer à la marche ultérieure de la maladie, ils conduisent le malade à l'anémie ou à l'obésité."

change in type is certain. The journals abound in such cases, and the experience of those who are accustomed to deal with the disease is always rich in incidents bearing on this point. I need not go beyond my own note-book to illustrate this.

CASE I.[1]—A gentleman had chancre and a faint eruption for which he took mercury in considerable doses during a few months. After ten years of health, he had syphilitic iritis, and a gummy destructive ulcer on the penis which resisted eight weeks of energetic treatment (caustics, etc.) at the hands of a surgeon, and cicatrized in three weeks under steadily increasing doses of the iodide of potassium.

CASE II.[2]—A medical student had chancre and indurated inguinal glands which were unmistakably syphilitic. He underwent treatment by small doses of mercury at my hands. His type of disease was so mild that he had no eruption whatever, nor any sign or symptom of disease except one indolent, indurated, post-cervical ganglion. Therefore he concluded that I was in error, and stopped his treatment entirely after a few months. In eighteen months I treated him for syphilitic hemiplegia. He had had no symptom meanwhile.

CASE III.—A physician got an insignificant sore, followed by a slight papular rash. He took no mercury, but was treated by cathartics. The rash went away, and he remained perfectly well for nine years. Then a lump appeared upon the top of his head, and remained stationary during eleven years. But now the patient had a fever, and, on getting up from it, the node spread, softened, and swept away an enormous piece of his skullcap. The wound healed kindly under the use of iodide of potassium.

CASE IV.[3]—A gentleman had urethral chancre. No eruption followed that he could remember. He certainly took no mercury, and remained well for twelve years, when he broke out with syphilitic ecthyma which disappeared after the use of arsenic for a time. Then his brain gave out, and was declared to be softening by one of the most noted experts in nervous disease in Europe. Finally this got better spontaneously, and a rapidly advancing, gummy, destructive ulceration invaded his soft palate. This got well immediately, with great improvement in his other symptoms, under the use of iodide of potassium alone.

CASE V.—A physician got chancre. A few mucous patches in the mouth followed, but, he stated, no eruption whatever. He took mercury for a year. Not a symptom appeared for thirty years. Then he died during a sharp attack of intelligential and convulsive troubles which he would not treat, not believing them to be syphilitic. The autopsy revealed a large gummy tumor in his brain.

CASE VI.—A gentleman got chancre followed by a light eruption. This was treated homœopathically and disappeared. Sixteen years afterwards he applied for treatment, being almost covered with nodes. He had ulcers in his throat and syphilitic lung disease. Steady improvement attended the mixed treatment.

CASE VII.—A gentleman got chancre and fell into the hands of an anti-mercurialist who dosed him freely and continuously for a year with iodide of potassium and sarsaparilla. His earlier symptoms were not severe. In one year ulcers appeared on both legs. The dose of the iodide was increased. The ulcers progressed in depth and area, three on the right leg measuring over one inch in diameter each. He now changed his physician. His new adviser discontinued the iodide of potassium and ordered protiodide of mercury. Improvement began at once. In two weeks the ulcers were cicatrized. He now ceased treatment, but, after two years, a gummy ulcer destroyed a portion of the septum of the nose; for this he consulted me.

[2] Ibid., p. 650.
[3] Van Buren and Keyes, Clinical Contribution, etc., Archives of Dermatology, vol. i. p. 108. Cases III. IV. V. and VI. were seen by me in connection with Dr. Van Buren.

These cases are not very exceptional. The list could be largely increased, but I restrict myself to these few cases because they sustain the point at issue from almost every side, and because some of them bear also upon other facts which will be used in subsequent portions of this paper. It will be seen that all these cases had a very light syphilitic attack in the beginning, and that they were all managed differently. Case I. had a light eruption, and took mercury in considerable doses for a few months. Case II. had no early eruption, and took a very little mercury for a very short time. Case III. took no mercury, but was treated by cathartics. Case IV. took no mercury, but was treated by balsams, because his chancre was urethral, and his malady mistaken for gonorrhœa. Case V. took mercury for one year, and remained well for thirty. Case VI. was treated homœopathically. Case VII. was treated for one year with iodide of potasium. I have had no patient who had been syphilized, but the seven cases cover nearly all the other methods of treatment: that by expectation; by cathartics; by diuretics (balsam, etc.); by mercury for a short time in large doses, for a short time in small doses, for a year in fair doses; by homœopathy; by iodide of potassium from the first—and all of these, starting mildly, turned out to be severe cases of syphilis.

It is indeed notorious how many bad cases of disease there are in which there has been very little early eruptive trouble, and in which the previous history of the patient shows treatment only during a few months. This treatment for a few months seems to be what nearly all cases get, and although very many of them, be they light or severe at first, escape serious subsequent trouble, yet there is no guarantee in the prevailing modes of treatment that they will so escape, *nor can a light beginning be counted upon to signify a type of disease necessarily mild.*

I have not thought it necessary to search among the array of corroborative cases which modern journals afford for material to further substantiate this point, preferring to adhere to personal cases, for the history of which I can vouch. I cannot, however, refrain from alluding to a recent article by Fournier,[1] a record of forty-seven cases of cerebral syphilis, and itself a strong argument against the too readily accepted maxim that mild syphilis needs but little treatment. Of the forty-seven cases only two were severe from the first, one was rather bad, thirty were ordinary cases, and fourteen "actually benign." One of these latter was the case of a medical student who got what is termed "un chancre de rien" (a mere trifle of a chancre), had a little papular rash and sore throat only, and took mercury for a few months. After seventeen years of calm, there came an explosion of syphilitic epilepsy, hemiplegia, hebetude, dementia, and death in spite of all the skill and care of Fournier and Ricord. My conclusions to this introductory section therefore are: (1) that all syphilis is severe and treacherous, and that further efforts are justifiable in attempting to perfect its treatment; and (2) that seemingly light cases need as thorough a course of medication as those cases which are apparently more severe.

II. *Is the internal use of mercury necessarily debilitating?*—Time would fail me should I attempt to go into this question exhaustively, yet upon its solution hangs the strongest possible argument for or against a con-

[1] La Syphilis cérébrale, est elle plus commune dans certaines formes de la diathése, etc., L'École de Méd., Aug. 30, 1875.

tinuous use of mercury. If mercury is an evil, if its influence is debilitating, then its use would only be justified by its ability to overcome some greater evil, some more debilitating agent; and it should be dispensed with in every case as quickly as possible. This indeed is the accepted view of the mercurial question in syphilis. I think, however, that it may be shown: (1) That mercury in minute doses is a tonic, and, (2) That mercury in minute doses has been in use in the profession as a tonic, in non-syphilitic cases, for very many years, and sanctioned by the highest authority.

(1) That mercury in minute doses increases the number of the red blood cells both in syphilitic and in healthy individuals, I think I have demonstrated with the hématimètre, publishing my results in the January (1876) number of the American Journal of the Medical Sciences. To that paper I must refer for details. Space will not allow me to reproduce the evidence here. I have, however, corroborated the conclusions therein reached by repeated, new experiments, during the present year, and these conclusions I beg leave to adduce in evidence now. They are based upon the counting of red blood-corpuscles in over one hundred different specimens of blood, which number has been greatly added to since the publication of the paper without occasioning any modification in the results at first arrived at. These conclusions are: (*a*) That 5,000,000 red corpuscles in the cubic millimetre of blood is a full, high average for the adult, healthy male, etc. (in New York); (*b*) That mercury decreases the number of the red cells when given in excess, especially in hospitals (this was also conclusively proved by Wilbouchewitch[1]); (*c*) That syphilis diminishes the number of red corpuscles below the healthy standard; (*d*) That mercury in small doses, continued for a short or for a long period, in syphilis, alone or with the iodide of potassium, increases the number of red corpuscles in the blood, and maintains a high standard of the same; (*e*) That mercury in small doses acts as a tonic upon healthy animals, increasing their weight. (Liegeois and Bennett cited.) In larger doses it is debilitating or fatal; (*f*) That mercury in small doses is a tonic[2] to individuals in fair health, not syphilitic. In such individuals it increases the number of the red blood-corpuscles.

I must again express regret that I cannot bring out the evidence here, which led directly up to these conclusions in such a way that I can see no possible escape from them, and, referring those interested to the original paper, I again ask to incorporate these conclusions as a part of my present argument. This proof of the tonic action of minute doses of mercury is scientific, but the demonstration from the *clinical side* is no less positive.

(2) We are all familiar with the well-known tonic consisting of a minute dose of corrosive sublimate in compound tincture of bark. I first learned it from the late Valentine Mott, who was loud in its praises as an "alterative" in the cases of strumous children. I cannot trace the authorship of this compound. It is very favorably mentioned as having "been long recommended both for scrofulous taint and the more declared forms of tuberculosis," in Copland's Dictionary of Practical Medicine, 1858;[3] and I find it spoken of as a preparation in common use, in a

[1] De l'influence des Préparations mercurielles sur la Richesse du Sang en Globules rouges et en Globules blancs. Archives de Physiologie, 4 et 5, 1876, p. 508.

[2] During as long a period as the experiments were kept up. Keyes, loc. cit.

[3] Vol. iii. p. 760.

lecture by Sir Astley Cooper, which appeared in the Lancet in 1823.[1] He praises it as an alterative "for the removal of chronic diseases in children." Modern ideas of "alterative action" are not very clear, and in connection with this mixture I never understood how mercury could be beneficial, until the truth flashed upon me, while counting blood corpuscles with the hématimètre, that mercury in minute doses was tonic in all cases in which it could be digested. I think that this tonic action of mercury in small doses must have had much to do with establishing the professional confidence in former days in so-called alterative[2] medication.

This conviction of the value of minute doses of mercury as an "alterative" (*i.e.*, tonic), not in syphilis but in all chronic disease, I find to be most deeply rooted in the minds of the older members of our profession throughout the country. I have received many letters, from far and near, from representative men, stating that they had inherited the faith from their preceptors, and had been for years in the habit of using minute doses of mercury, long-continued, as an alterative in chronic debilitating disease; that they had used it empirically, but with good effect. I have received similar answers from all the older men whom I have questioned. What can be stronger evidence than this that mercury in minute doses is tonic, increasing the vitality of the individual; and when to this is added the scientific proof, by actual counting, that mercury increases the number of the red blood-corpuscles, the chain of evidence seems complete. It may be well here to mention a remedy on which many of the profession in New York were accustomed to rely some years ago with confidence for the cure (or certainly the relief) of Bright's disease. It was two grains of corrosive sublimate in an ounce of tincture of the sesquichloride of iron. The dose was ten drops (not minims), containing about one-fiftieth of a grain of bichloride of mercury, a very fair tonic dose; and that improvement attended its use in many cases, is unquestionable. Finally may be cited the popular sanction of minute doses of mercury as a tonic which is found in the history of Swaim's Panacea,[3] a nostrum at one time in very general use. This remedy consisted of a minute quantity of corrosive sublimate in compound syrup of sarsaparilla. Swaim is believed to have gotten the idea from an old book, his first business having been that of a book binder.

While then all the evidence goes to show that minute doses of mercury are tonic, out of syphilis as well as in it, the proof is equally strong that mercury in large doses is debilitating, if at all continued, whether in syphilis or out of it. This is proved by history, by clinical experience, and by actual blood counting with the hématimètre, as has been shown by Wilbouchewitch and by myself, in the articles already referred to.

[1] Vol. i. p. 111.

[2] J. Kent Spender, of London, refers to the action of corrosive sublimate (Journal of Cutaneous Medicine, No. 15, 1870, p. 187), saying that it indirectly promotes the nutrition of several tissue elements, and speaks of Dr. Billing's mention of its action as tonic. In a letter to me, Dr. Spender says that Billing (First Principles of Medicine, 5th ed. 1849, p. 109) states that the "tonic" action of mercury illustrates the rationale of the operation empirically called "alterative." He does not enlarge or explain further.

[3] Dr. E. R. Squibb, of Brooklyn, informs me that this nostrum, appearing about the year 1825, was extensively advertised, and enjoyed unbounded popularity, bringing great wealth to its inventor. In 1828, Prof. Hare, of the University of Pennsylvania, discovered mercury in the mixture. He published the fact in the Amer. Journ. of Med. Sciences, vol. iv., 1829, p. 530, whereupon Swaim denied that the "Panacea" contained mercury. In fact mercury does not *now* seem to be one of the ingredients. Mr. Neergaerd analyzed a specimen of Panacea for me, but failed to find any mercury.

III.—*When is mercury useful in syphilis? Has it any control over the late symptoms?*—If it be once admitted that mercury is useful during any stage of syphilis, the proof that it is a tonic theoretically establishes its value during all stages of the disease; for the hématimètre on the one hand, and clinical observation on the other, prove conclusively that syphilis is essentially a debilitating malady, and that it lessens the number of the red blood-cells. Yet mercury is not alone tonic, it is antidotal to syphilis; not only generally to syphilitic symptoms, but specifically when locally applied, as Koebner[1] has shown, particularly for condylomata, referring also to Ch. Hunter and Hebra; and as Monti[2] has demonstrated by causing the local disappearance of patches of eruption by injecting the bichloride subcutaneously into them, while other patches at a distance remained comparatively unaltered. In a general syphilitic eruption, the advantage of combining local with general means is strikingly shown by the much more prompt disappearance of lesions which have been subjected to the local use of mercury, than of the same lesions elsewhere seated and not locally treated. This I have repeatedly noticed.

Every one admits the power of mercury in postponing and modifying the earlier symptoms of syphilis, and of shortening their course when they do appear. Even the anti-mercurialists allow this, their claim being either that mercury prolongs the attack on the whole by postponing the symptoms, since the disease must run its course—or that it suppresses the virus and causes the appearance of tertiary lesions by debilitating the constitution, or in some other way. No statistical or other evidence with which I am familiar has ever established either of these assumptions,[3] while the almost universal advocacy of mercury in syphilis, in one form or another, by a majority of the best minds in the profession in all countries, goes far to show that this is the only honest remedy for syphilis with which the profession is familiar. As for the two points of the anti-mercurialists—that mercury used early only postpones the symptoms, prolonging the total duration of the disease, and that tertiary symptoms are due to mercury—if time allowed, any number of cases might be cited in opposition to this view; such as Cases III. and IV. of this paper, in which, no mercury having been used, the disease was in full force after twenty-one and fifteen years respectively, in the most advanced tertiary type; or Case VII., in which mercury cured

[1] Archiv f. Derm. u. Syph., B. I., S. 628; quoted from Jahresber. d. schles. Gesellsch. f. vaterländ. Cultur.

[2] Jahrbuch. f. Kinderheilkunde, 1869, S. 381. Beobachtung über die Behandlung der Syphilis congenita et acquisita mittelst subcutaner sublimatinjectionen.

[3] Undoubtedly statistics exist on both sides of the question, but they fail to prove anything positive. Quite recently Jullien (Gaz. Hebd., Sept. 18 and Oct. 2, 1874), in a statistical paper attempting to establish the proportion of cases of tertiary disease occurring in those who had taken mercury for their earlier symptoms, as compared with those who had been otherwise treated, found in 218 cases of tertiary disease that 59, more than one quarter, had not taken mercury, while all the rest had taken it. The number of cases of nervous syphilis he noted to be much greater proportionally in those who had taken mercury. All this, however, proves nothing except that syphilis naturally runs on to tertiary symptoms when untreated. Statistics cleverly handled are capable of proving almost anything in relation to syphilis, because the disease itself is so capricious. In this case the statistics were made up from letters received from physicians in France, England, and Italy, and undoubtedly in these countries three-quarters of the well known physicians give mercury early in syphilis, and it would be but fair that three-quarters of the cases of tertiary syphilis found should turn out to have taken this remedy. This is especially probable when the statistics are compiled by one who is no lover of the drug, and his figures lose all value when it is remembered that there is no record of the cases which did not become tertiary under the mercurial and anti-mercurial courses.

tertiary ulcers, which failed to improve under fair doses of iodide of potassium, in a patient who had been treated by the latter remedy alone for a year after his chancre appeared.

That mercury retains its value late in syphilis is amply illustrated by the well-recognized power of the mercurial, general fumigation, in many advanced forms of syphilitic ulceration, late in the disease; by the great value of what is known as the mixed treatment, especially in controlling peculiarly chronic and grave symptoms of late syphilis; and by the numerous cases of nervous syphilis found in the journals of the day, in which the turn in the symptoms is noted as the point at which the gums became touched. Occasionally a case is found in which the customary forms of iodine cannot be borne late in syphilis, or in which they do not seem to meet the requirements of the disease. Under these circumstances an appeal to mercury alone will often yield a victory over symptoms until then rebellious. Case VII. of this paper is in point, mercury having succeeded where iodine had failed. While then it seems not doubtful that mercury retains its power in every stage of syphilis, yet it is no less true that it cannot be relied upon in emergencies in certain, especially the gummy, forms of tertiary disease. Here the different preparations of iodine take the lead.

As a final illustration of the power of mercury over tertiary lesions may be cited its undoubted value in inherited syphilis. Here the lesions are grouped in a disorderly manner—tertiary, perhaps gummatous, disease of the bones, lungs, kidney, thymus gland and liver, often accompanying secondary symptoms on the skin and mucous membranes—yet in these cases mercury is generally relied upon, and often proves capable alone of routing the enemy. I conclude, therefore, that mercury is of value during the whole treatment of syphilis, in minute doses throughout, for its tonic and anti-syphilitic action; in larger doses, as the occasion arises, to suppress outcropping symptoms, the action here being purely anti-syphilitic, and not tonic.

IV. *When is iodine useful in syphilis? Can it replace mercury in any stage of the disease?*—In studying this point, I have again had recourse to the hématimètre to watch the effect upon the red blood-corpuscles of the internal administration of the preparations of iodine. My conclusion, based upon a considerable number of blood-counts made by myself, and many by my friend Dr. L. A. Stimson, is that iodide of potassium is a tonic, and increases the number of the red blood-cells. It does this in all stages of syphilis. I have not yet tried its effect upon the healthy individual, but notably in some experiments by Dr. Stimson this point came out, that while iodide of potassium, given immediately after the appearance of a chancre, increased the red blood-cells with proportionally greater rapidity than did mercury given under similar conditions (for the effect of mercury during the first depression preceding the outcrop of the earliest eruption is often very slight), yet, in spite of this greater increase in the number of the red blood-cells, the administration of iodide of potassium did not retard the appearance of the secondary symptoms to the same extent as did the use of mercury. This fact corresponds to the well-known results of the experiments of Grassi, who determined that iodide of potassium increased, while mercury decreased, the proportion of the red blood-cells to the whole mass of blood when used in syphilis. In Grassi's day, mercury, when used at all, was

always given in excess, and his conclusions, although obtained by chemical methods mainly, are undoubtedly accurate.

These statements of Grassi have been made use of to construct a rule of practice; namely, to give iodides and tonics early in syphilis, avoiding the supposed depressing influence of mercury. But when it appears that the iodides do not seriously interfere with the outcrop of the early eruptions, while mercury certainly does; and when it turns out that mercury in small doses (but large enough to greatly modify the disease) is tonic, the rule of practice founded on Grassi's experiments fails to find any scientific support, and must fall to the ground. Case VII. in this paper illustrates this point. This patient was dosed with iodide of potassium for a year, but his early eruptions appeared none the less, although they were undoubtedly mild, and his tertiary symptoms came on in due time, perhaps as early as they would have come had no treatment been used. Iodine doubtless has some modifying influence over syphilis during its whole course, but not enough to make it wise to substitute this drug for its more powerful rival early in the disease.

I see no reason to believe that iodine has any eliminative power in syphilis, and I have failed to discover any evidence to show that it tends to prevent relapse. That it holds a place, however, in the treatment of syphilis, is undoubted; and a very high place it is. When tissue-infiltrations take place; when the lesion approaches the gummatous type; when there is considerable connective-tissue proliferation, especially if it takes place rapidly, whether the affection is of an external or of an internal organ; when nodes form upon the bones; when the cartilages begin to soften; when ulceration is spreading rapidly, then the preparations of iodine used unsparingly for the symptom are the right hand of treatment. Here nothing can replace iodine. To its benign influence, when well assimilated and rapidly pushed, the most formidable lesions yield a quick response.

In certain of the chronic lesions occurring late in syphilis, the power of mercury is greatly enhanced by combining some preparation of iodine with it; but where the lesion is a gumma, mercury may be dispensed with at once, and entirely, and iodine pushed with a lavish hand until the symptom yields. Mercury, however, must be resumed to seal the cure and prevent relapse, and it must be given with long patience and scrupulous care that it is thoroughly assimilated. In syphilis, therefore, when the lesion is gummatous, no matter where it is situated, iodine may replace mercury with profit to the patient; but under no other circumstances can it take the place of this drug, although it may often be advantageously combined with it. Iodine is indeed what many have considered mercury to be, a remedy not at all curative of syphilis, but causing the disappearance of certain of its symptoms. A curative agent it is not, because it has little if any power of shortening the duration of the disease, of keeping off or modifying many of its symptoms, or of preventing relapse.

V. *Does iodine act by liberating mercury lying latent in the tissues?*—I think that this question may be briefly disposed of in the negative. That iodine taken at the same time renders a given quantity of mercury more active, is probable, this being perhaps the secret of the success of the mixed treatment for chronic obstinate lesions, not gummatous. But whatever power as an anti-syphilitic remedy iodine possesses, it probably exercises by its merit as a tonic, increasing the number of red cells in

the blood; for this it does even early in the disease, in spite of the depressing influence of the virus.

When a patient has been carrying a certain amount of mercury without showing it in the mouth, the sudden administration of iodide of potassium may call forth symptoms of salivation. Indeed, iodides given alone, in some exceptional cases, have produced quite marked symptoms of mild salivation. But a little positive evidence outweighs any amount of negative testimony, and whatever power iodine may have in rendering mercury active, still, in its own sphere, in controlling gummy exudation in any of its forms, iodine does not yield a hair's breadth to any remedy, or demand the least assistance from mercury. An excellent case bearing on this point was printed editorially in the Gazette des Hôpitaux for January 28, 1860.[1] Cases III. and IV. of this paper are directly in point, iodine alone having cured patients who had never taken mercury. Case VII. might be referred to as evidence on the other side; but, as I have already stated, some forms of tertiary disease, notably some of the ulcers, seem to demand mercury for their treatment, and yield to it much more promptly than to iodine. In this case, also, I could not ascertain to what extent the iodide had been pushed, and at best the evidence is negative, while the other is positive.

The late Prof. Boeck, of Christiania, informed me, while in this country, that, when tertiary symptoms occurred in his patients who had been treated solely by syphilization, he was in the habit of using iodide of potassium with good effect, combined with a continuance of syphilization. In these cases surely there was no antecedent mercury, the liberation of which could do the work. And finally, in proof that the iodine possesses the power, it is only necessary to recall that, in those frightful cases of devastating disease which we sometimes meet with, and which yield to the iodides, the dose must not be restricted, but pushed with rapidity up to the point of tolerance, the amount of the dose assimilated being in direct relation to the rapidity of cure.

VI. *Should treatment be continuous or interrupted?*—The answer to this question has already been brought out in what has been written. The continuous use of iodine need hardly be considered, for I feel unable to include this drug among the curative agents of syphilis. It has enormous power in overcoming certain symptoms, but as these symptoms are intermittent, the use of iodine should also be interrupted. While the symptom lasts, and for a certain time afterwards, iodine is called for; but as it does not prevent relapse, or shorten the whole course of the disease, there is no occasion for its prolonged use. Mercury, on the other hand, has received the palm as the anti-syphilitic, at least the symptomatic, anti-syphilitic, remedy, *par excellence*, from a majority of the best medical scholars and authorities up to the present time. It is an antidote to the poison, whatever the nature of that poison may be. I think that the results of blood-counting by the hématimètre, used upon the blood of syphilitic patients who had taken small doses of mercury continuously for long periods (over three years),[2] proves that mercury is not debilitating, but, indeed, a tonic, when used in minute doses.

[1] Although the writer states that he thinks iodine often does not act well unless mercury has been previously used.

[2] Keyes, loc. cit.

Clinical experience also has convinced me of the value of the continued treatment. I have employed it in all cases, light or severe, in which I could control the patient, since the early spring of 1869. Generally I have not commenced treatment until the post-cervical and epitrochlear, glandular engorgement, and an eruption, have come to confirm the diagnosis. My observation has included nearly all the cases of my partner, Professor Van Buren, and I have to thank him for his kindly suggestions which have led to many of the steps in this investigation, an investigation which has convinced us both more than ever of the value of the uninterrupted use of mercury in small doses in the treatment of syphilis. It has become a rule with us, to which we find but few exceptions, that patients, after acquiring syphilis, remain in as good and often in better health while under treatment than previously. Severe cases are the rarest of exceptions, and tertiary symptoms (in those treated from the start) nearly unknown. Slight localized lesions, such as a scaly spot on the palm, a cluster of a few papules here or there, appearing from time to time, are, customarily, all that mark a continuance of the disease, except the lesions of the throat and mouth. Slight ulcers about the throat, mucous and scaly patches in the mouth and on the tongue, are apt to persist and recur at intervals, for long periods. These are the main, very often the only, symptoms requiring attention after the first eruption has passed, and they respond to local measures, or to a slight increase in the strength of the general treatment.

Usually the continuous treatment is kept up for from two and a half to three and a half years, or even longer, and in all cases, if possible, until six months, and sometimes a year or more, after the appearance of the last syphilitic symptom. Many of the patients so treated are now married and raising healthy families—themselves to all appearances perfectly well.

Of course it is impossible to state how many of these patients are absolutely exempt from any further relapse. Seven years and a half are not sufficient to pass final judgment on any method, but against other methods may be urged: (1) That the numerous bad cases constantly met with have all been treated by them; (2) That salivation is certainly harmful; (3) That mercury, not pushed to salivation, but used in large doses, has been proved to be debilitating by the hématimètre (Wilbouchewitch, Keyes), by clinical experience, and by experiments upon animals (Liegeois, Bennett, Wilbouchewitch, and others); (4) That the intermitting treatment is simply symptomatic, and virtually makes one confess that he has no remedy for the disease, but can only moderate the symptoms until such time as they may see fit to cease to reappear.

For the continued treatment with minute doses of mercury it may be urged, on the other hand: (1) That it has given good results thus far (seven and a half years); (2) That it is scientifically and theoretically correct to use continuously for a given evil an antidote which can itself be proved to be beneficial to the individual, be he sick or well; (3) That it seems proper to use an antidote continuously against a poison which is continuous, although having long periods of latency. For the poison must be continuous and still present in the tertiary stage, although it has then lost much of its virulence and power of transmissibility. How else can we account for the undoubted fact that parents with tertiary disease may produce children with inherited syphilis (I have notes of such cases), and inherited syphilis is well known to be capable of transmitting itself in full force to the nurse and other healthy persons by contact; (4)

That this continued treatment is only a modification of the "coup sur coup" plan, so widely practised, for the quantity of mercury is augmented upon any outcrop of symptoms, the minute, continuous dose being maintained in the intervals. It is, indeed, not very widely different from the common, symptomatic, interrupted treatment, yet I cannot but believe that it is a great improvement upon both of the ordinary plans.

VII. *General outline of a course of treatment in a typical case.*—When the first eruption appears, or sooner if by confrontation or other sure means the existence of syphilis is placed beyond any possible doubt, my habit has been to put the patient upon a mercurial, and to increase the dose, slowly if there is time, more rapidly if the eruption is pressing, paying all possible attention to hygiene, food, surroundings, care of teeth, etc., until slight diarrhœa with colicky pain is complained of, or until the gums just begin to be touched. The amount required to produce this effect is now known to be the patient's dose, beyond which he cannot safely go without aid from opiates, or changing the form of administering the drug, and at which, if it is maintained, the effect on the general health will be injurious. Having found this dose, it may be maintained, if the eruption demands it, by giving opium, bismuth, rice, milk, etc., until the symptom yields; then it should be reduced to one half, or a little below this point (this dose will prove tonic to the patient), and there maintained day after day, continuously, year in and year out, waiting for other symptoms.

Should such symptoms occur, for there may be none except mucous patches, which local means will relieve, I think it is well to give the patient mercurial baths,[1] when practicable, two or three times a week or oftener if they do not prove depressing, maintaining the same internal dose. Instead of this, the half dose held in reserve may be immediately or gradually added to the tonic dose, or inunction may be practised, until the symptoms are subdued, when the tonic dose is to be again resumed and unremittingly continued.

Later in the disease, should any of those symptoms supervene which are known to be favorably influenced by iodine, the iodide of potassium or sodium may be combined with the mercurial (preferably with the biniodide of mercury), and the two continued (mixed treatment).

Should cerebral symptoms come on; or bones, or nerves, or muscles, or viscera, or any of the tissues become involved in any of the forms of gummatous growth (this, however, I have not yet seen in any case where the directions have been strictly followed from the first); then the iodides are to be used unsparingly for the symptom, it being of little importance whether the mild mercurial is continued for the time being or not.

Many deviations from this simple course may be necessitated by varying cases, especially when the continuous treatment is only commenced late in the disease. I think that a case treated from the first symptom should receive mercury continuously, in small doses, for a period not less than two and a half years, or, in any event, until at least six months have passed after the entire disappearance of the last clearly syphilitic symptoms. It is hardly necessary to add that all treatment may be sus-

[1] Two drachms of black oxide after a few minutes of steam (not hot air), the whole bath to last not over twenty minutes, is a fair average.

pended without ultimate disadvantage should any acute disease accidentally occur within the limits of this time.

My time has expired, and it would be hopeless for me to attempt to take up a consideration of exceptional cases, either of patients such as those who cannot take mercury or iodine, or of peculiar forms of disease, or surrounding circumstances, where these remedies seem powerless, and where an appeal to change of air, or to derivation by the bowels (Zittman's decoction), or derivation by the skin (syphilization or tartarization), seems to effect more than can be done by following the rules established by success in the majority of cases.

I cannot consider the value of mercury locally, as a means of treatment of the lesions, or of other local remedies; nor the relative value of iodine used as the tincture (internally), or as the iodide of potassium, of sodium, of ammonium, of calcium, or of amylum, or as metallic iodine with albumen, or as iodoform; nor of the varied use of these agents by the stomach or rectum. My remarks have been general, and intended to apply to the typical case, and I have endeavored to group them so as to lead up to the following negative and positive conclusions, which I now beg respectfully to lay before you, and on which I ask the expression of your opinion.

Negative Conclusions.—Views for which there would seem to be no positive foundation in fact:—

I. Syphilis commencing mildly needs but little treatment, and does not require mercury.
II. Mercury given internally is necessarily debilitating.
III. Mercury is only useful in secondary syphilis.
IV. Iodide of potassium is of considerable value in secondary syphilis.
V. Iodide of potassium is of no value unless preceded by the use of mercury.
VI. Iodide of potassium acts by liberating mercury which has been lying latent.

Positive Conclusions.—Propositions which, in the present state of our knowledge, may be affirmed:—

I. Mercury is an antidote to the syphilitic poison, and of service in controlling all its symptoms in all (even the latest) stages of the disease, its power over gummata being least marked, and not to be relied upon.
II. Mercury in minute doses is a tonic.
III. Iodine cures certain symptoms of syphilis, but does not prevent relapse.
IV. The use of mercury, long-continued, uninterruptedly as far as practicable, in small doses, from the time of the earliest eruption, constitutes the best treatment of syphilis.

Discussion on Dr. Keyes's Paper.

After the reading of the preceding paper, Dr. L. D. Bulkley, of New York, said:—Dr. Keyes's first positive proposition requires qualification, for mercury is very injurious in gummatous cases. An exception should also be made for certain rare cases. I had a patient who had intercourse on the fourth of July; a chancre appeared in due course of time, and the man came to me for treat-

ment in the following September. I observed this case constantly for a year and a half, and it developed all the symptoms possible during that period. Yet that man could not from the first take mercury without positive injury.

Dr. Keyes said:—I myself know of a worse case, in which the patient lost both eyes from the disease, but could not take mercury in any form. The proposition, however, does not profess to cover every idiosyncrasy.

Dr. R. W. Taylor, of New York, said:—The paper gives distinctly and clearly what many books leave in doubt, namely, the time of beginning mercurial treatment. I think that there are many good reasons for using mercury before the secondary lesions begin; in cases in which the induration of the chancre is marked, it will melt away under the influence of mercury. I have, however, seen cases in late stages in which too much reliance had been placed upon mercury. For the late lesions of the skin, the iodide of potassium will be found very useful.

Dr. Keyes said:—I recall two cases in which the chancre appeared upon the lip; in these, having no doubt that the chancres were syphilitic, I gave mercury at once and with good effect.

Dr. Bulkley said:—If the diagnosis is made at first, there is no reason why mercury should not be at once administered. If I had the slightest suspicion that a sore was syphilitic, I should feel it my duty to give it immediately.

Dr. Taylor said:—In any case of doubt, however, the future of the patient is not imperilled by waiting for the further development of the disease. I am fully convinced of the tonic qualities of mercury, and have known it to be used with better effect than iron or quinia in cases in which the latter are the common remedies. Pains at night, which refused to yield to morphia, I have known to be allayed by an eighth of a grain of mercury daily; mercury is also very efficient in controlling syphilitic fever.

Dr. William Oldright, of Toronto, said:—I would ask Dr. Keyes to specify the particular symptoms for which he would give iodide of potassium, and to say whether iodide of potassium is better than other forms of iodine?

Dr. Keyes said:—In lesions of the joints, nerves and viscera, tubercular skin affections, etc., it is well to give the iodide. Its action is so ready and so plain when given in large doses in such cases, that in a week or ten days the physician can tell whether he is upon the right track, and, if he finds that he is not, can fall back upon mercury. Other iodides may be used, but I give the preference to the iodide of potassium because it is the most easily assimilated.

Dr. Bulkley said:—Mauriac has presented a series of cases of bone lesions in which the iodide failed and mercury had to be resumed; I myself, too, have seen such a case.

Dr. Keyes said:—I have not seen many cases of bone lesion early in the disease, but in those which I have seen I have not interrupted the mercurial course, though I have given the iodide in connection with it. I know that there are some tertiary lesions which do not yield to the iodide, but the rule is that it is of benefit to them.

Dr. Taylor said:—Where troubles of the fibrous tissues and bone lesions come on early, I have always used the iodide; they will not yield as well to mercury alone as to it and the iodide combined.

Dr. Charles Heitzmann, of New York, said:—I would ask Dr. Keyes whether, having said that the iodide of potassium will not prevent a relapse, he means to assert that mercury will prevent a relapse in syphilis?

Dr. Keyes said:—I would not make such an assertion absolutely. I can only speak from my own experience, and I am well satisfied with the course of my patients under the mercurial treatment. Mercury has caused them to have better health than they enjoyed before they contracted syphilis. I cannot say that they will not have other symptoms, but I am convinced that the continuous treatment with mercury is the most scientific, the most philosophical, the most harmonious, and in fact the best.

Dr. HEITZMANN said:—I have employed Dr. Keyes's method of treatment, and have found it unable to prevent a relapse.

Dr. TAYLOR said:—Generally, after two or three years of mercurial treatment, the patient is practically cured as a syphilitic, and it seems to me useless to debate about the unimportant disorders that may subsequently occur.

Dr. HEITZMANN said:—I have seen, in Vienna, cases of mild beginning, which have got well without any decided treatment, and others that have required the most careful management. I believe that syphilis can be cured, but whether the cure should be attributed to the skill of the physician or to other causes, no one can say.

Dr. BULKLEY said:—Instead of giving mercury every day of every month, while the treatment lasts, I generally keep my patients under constant treatment for from three to six months, then let them drop one week a month, for three months, then two weeks a month, and sometimes let them alone for a month at a time; thus they do not take so much mercury, but keep the system always under its influence.

Dr. TAYLOR said:—I would ask Dr. Keyes whether, after uninterrupted treatment for two years and a half, he has not found a decrease of blood-corpuscles, and been forced to cease treatment, and after a while resume with increased doses?

Dr. KEYES said:—The reverse of this is the result of experiments. One-twelfth or one-eighth of a grain of the bichloride, three times a day, is a large dose; one-thirty-fifth to one-fiftieth of a grain is a tonic dose. Wilbonchewitch gave large doses, and kept his patients housed in close hospitals, and of course the number of their red corpuscles decreased. I had a patient who after continuous treatment for two and a half or three years had six millions of red corpuscles to the cubic millimetre, the best blood-count I have ever known. This patient has never had any trouble since, and has become the father of a perfectly healthy child.

Dr. TAYLOR said:—By constantly taking mercury, the patient becomes tolerant of it, and therefore, as Fournier has said, the treatment should be stopped for a time in order to allow the system to recover and become more susceptible to its action when again administered. Moreover, as syphilis does not show itself by long and continuous evolutions, it is consistent to treat it intermittingly; both before and since reading Fournier's paper, I have used the intermittent treatment with excellent results.

Dr. KEYES said:—Tolerance is not established when mercury is given in tonic doses. The intermittent treatment is nothing more than symptomatic treatment, leaving the patient in the intervals to take care of himself; my plan is to keep the patient in good condition by giving him the tonic dose until the symptoms appear, and then to give him the anti-syphilitic dose.

Dr. L. A. DUHRING, of Philadelphia, said:—The only way of arriving at a satisfactory conclusion as to the best manner of administering the drug, is by observing series of cases treated by both methods. In my practice I use both methods, making my selection with reference to the patient himself and the peculiar circumstances of his case. I see advantages in both methods. I think that the plan suggested by Dr. Taylor is practically the best, and that that suggested by Dr. Keyes is often impracticable.

On motion, the propositions appended to Dr. Keyes's paper were adopted as expressing the opinion of the Section.

THE TREATMENT OF SYPHILIS.

BY

CHARLES R. DRYSDALE, M.D.,

SENIOR PHYSICIAN TO THE METROPOLITAN FREE HOSPITAL, PHYSICIAN TO THE BOLSOVER STREET LOCK HOSPITAL, LONDON.

[COMMUNICATED BY THE SECRETARY.]

IT is, in my opinion, a most fortunate circumstance that the members of the International Medical Congress at Philadelphia have determined to discuss the treatment of Syphilis, because it cannot be said that any clear body of doctrine has as yet been laid down as to how this should be carried out, whilst there never has been at any time in the history of medicine so good an opportunity for coming to a correct conclusion on the matter.

Syphilis is now well known to have been quite a new disease in Europe, somewhere about the end of the fifteenth century. As to whether it had existed formerly in America and Japan, it seems to me that our historical works do not enable us to come to any clear conclusion. At its first outbreak, syphilis was so perfectly an unknown disease that the regular physicians confessed that they did not know how it should be treated, and it was handed over to a host of illiterate persons who, as usual, treated the disease so badly that at the end of the fifteenth century it was, it seems, a terrible and revolting spectacle.

Mercury was employed, probably in the form of inunction, in the treatment of syphilis, as early as 1497; but Paracelsus was the first to recommend its administration internally, about the year 1570. At first, mercurial inunction was confined by physicians of repute to cases of true syphilis, before the confusion-period when gonorrhœa and soft sores were put down as belonging to syphilitic inflammation; but, gradually, this method of cure was applied also in cases where no true syphilis was present; and, as salivation was caused, much misery and disease were occasioned by the use of the drug. It was chiefly from this reason that the period of the Peninsular War was such an important one in the history of the treatment of the disease. In 1812, whilst that war was going on, Dr. William Fergusson wrote a letter on the treatment of syphilis, which was read at a meeting of the Royal Medical and Chirurgical Society of London. In this letter, he showed that the natives of Spain, although entirely untreated by mercury, generally made good recoveries from their venereal ulcers, whilst the British troops had their sores in very many instances terribly aggravated by the careless use of mercurial inunction. This letter of Dr. William Fergusson was followed by a number of important experiments made by Rose, Guthrie, Hennen, John Thompson, of Edinburgh (the teacher of James Syme), Desruelles, and especially Fricke, of Hamburg, all of these observers having treated both soft and hard sores without mercury. On the whole, so great was the advantage which accrued in their experience from the disuse of salivation in gonorrhœa and soft sore, that most of these

authors were strong anti-mercurialists, for a long period of their practice, at least.

About the year 1838, M. Ricord entered on his office as *chef de clinique* of the Hôpital du Midi, of Paris; and from that time we may date most of the accurate ideas we possess about venereal diseases. He made it abundantly clear that gonorrhœa was not a syphilitic symptom, and, hence, it was no longer treated with mercury. He next withdrew soft sores from mercurial treatment, and thus confined his attention to the mercurial treatment of true syphilis. For many years, M. Ricord treated the hard sore and its sequelæ by a six months' course of iodide of mercury, in small doses; of late he has prolonged the time of treatment to about a year. The great surgeon of Edinburgh, Mr. James Syme, and his distinguished pupil, Professor Hughes Bennett, most vigorously protested against the long mercurial courses advised by Ricord and his followers, and the Edinburgh School has of late years been, on this account, on the whole, anti-mercurialist in its tendencies.

The author of this essay, in a pamphlet published in 1863, adopted anti-mercurialistic views, and treated from 1860 to 1870, his syphilitic patients entirely without mercury, whether for the hard sore, or for secondary or tertiary lesions. The result of this treatment went to show that many cases of true syphilis were very mild indeed, the whole disease consisting in such cases in a few discrete eruptions, with occasionally slight alopecia, and sore-throat, coming after indurated sore with enlarged and indurated inguinal glands. Tertiary symptoms, however, pretty frequently supervened after non-mercurial treatment of the early symptoms of the disease, in the form of gummy tumor of the testicle, sloughing sore-throat, or ozæna, with destruction of the small bones of the nose. Hence, the lesson taught by abandoning mercury for a time was that syphilis was not unfrequently a mild disease; but that it also was not uncommonly a grave affair.

At the present juncture, it would seem to me, from the evidence given in 1867 by the members of the Société de Chirurgie, of Paris—Diday, Verneuil, Lefort, etc.—as well as by that most learned of all writers on syphilis, M. Alfred Fournier, of Paris, taken in conjunction with the evidence of Henry Lee, Hutchinson, De Méric, and Berkeley Hill, in London, that mercury, when administered very carefully, and in small enough doses, so as never to excite salivation in the slightest degree, and for a sufficient length of time, has (what has been styled perhaps rather sanguinely) some *antidotal* power in extinguishing the virus of syphilis. Mr. Hutchinson, who is fond of hypothesis in this matter, speaks of mercury destroying the *germs* of syphilis, and affirms that if mercury be given in the period of the initial lesion, it will often nip the disease so completely in the bud that not a trace of secondary syphilis may appear. Hutchinson gives very small doses of mercury and chalk, not more, as I understand him, than half a grain, twice daily; but he has never clearly indicated for how long a time he keeps up this treatment in the primary and secondary periods of the disease. M. Alfred Fournier is the most strenuous of all modern defenders of mercury in the treatment of syphilis. In his lectures, delivered at the Lourcine Hospital, of Paris, he boldly alleges that, without doubt, of all causes for the appearance of tertiary lesions, not one is so potent as the negative one—omission of mercurial courses from the early treatment of this disease. He is very careful not to advise short courses of mercury, or to lay down hesitating rules as to the length of time it should be given. He is no believer in the

possibility of diagnosing mild from severe syphilis, as Diday thought he could do. All hard sores and secondary eruptions are, accordingly, treated by Fournier for the first two years of the existence of syphilis by means of interrupted courses of the iodide of mercury, so as to administer that medicine for some ten months in the course of the two years. His dose is from five to ten centigrammes of the green iodide of mercury daily, *i. e.*, from about three-quarters of a grain to a grain and a half of the iodide in the twenty-four hours.

Although I am not entirely persuaded of the complete truth either of Hutchinson's germ-theory and the antidotal powers of mercury, or of Alfred Fournier's theory of prophylaxis against tertiary symptoms, I have been so far influenced by the views of these able syphilographers, that I have, of late years, given rather lengthened courses of the green iodide of mercury, or of mercury and chalk, to all my syphilitic patients in the early periods of their disease. Commencing with two-thirds of a grain in twenty-four hours, accompanied by two grains of extract of hyoscyamus, in the form of a pill, I found myself constrained to lessen the dose to one-third of a grain of the green iodide, as a usual formula. Even with this small dose, salivation not unfrequently occurs, if the patient be not carefully watched. This result of this treatment has not hitherto been in any way discouraging. No accident of gravity has ever occurred with these doses, and the patients seem to pass through the roseolar and eruptive period (as well as through the iritis, which occasionally ensues even in the midst of a mercurial course), in a very favorable manner. I cannot, as yet, pronounce distinctly whether these prolonged courses have warded off tertiary symptoms, but trust that, by this apparently innocuous treatment, I may have in some cases prevented the appearance of that dreaded stage of the disease.

It must not be supposed that Fournier has carried all his Parisian medical brethren with him when he proposes this long-continued mercurial treatment of syphilis. I found, indeed, M. Lancereaux, in a conversation which I had with him in the month of May last, 1876, much opposed to Fournier's idea that long mercurial courses were capable of preventing the occurrence of tertiaries. It will be remembered, by those who are familiar with the literature of syphilis, that Diday, in his work on the "Natural History of Syphilis," published in Paris in 1863, was of opinion that no particular cause for the appearance of tertiaries had been shown to exist. M. Lancereaux shares, it seems, this conviction with Dolbeau and Perrin, as declared in their speeches at the Société de Chirurgie in 1867, and is of opinion that no mercury need be given either for the hard sore or the secondary rash, because these may disappear of themselves. He would reserve mercurial treatment for the tertiary period of the disease. M. Després never administers mercury at any period of syphilis, but trusts to iodide of potassium as a remedy for tertiary symptoms. M. Hardy, in common with other physicians, gives mercury conjoined with iodide of potassium in the tertiary period; and the school of Aix-la-Chapelle, in Prussia, seems to prescribe the inunction cure in all periods of the disease.

Before leaving the question of the treatment of the early periods ot syphilis, I cannot refrain from saying one word as to the confusion which has recently been occasioned by the writings of the late Dr. Morgan, of Dublin, and of Mr. Jonathan Hutchinson, as to the nature of the soft sore, and the tendency of these doctrines to cause a revival of the treatment of that lesion by mercury. I beg to protest with all my

powers against any but local treatment of soft chancre. It is no more requisite to administer mercury in that disease, in order to ward off syphilis, than it is to give it in gonorrhœa. Mr. Hutchinson asserts that *mixed* sores are very common, and seems to hint that it might often be safer to administer the antidote to syphilis, on the chance that the soft sore might be followed by the hard one; but such practice is, in my opinion, a step backwards to the doctrines which were dominant when Ricord and Bassereau made their great discoveries.

Supposing that we have been unable to prevent our patients from arriving at the tertiary stage, or that they have come to us already affected with some gummy deposit, whether in the skin, the mucous membranes of the throat, or the viscera, what should then be our treatment? For my part I have no difficulty in saying that the great remedy for the gummy period of syphilis is the iodide of potassium; and that it is often most dangerous to delay in administering this drug. Mercury is often, I am persuaded, entirely useless in the case of tertiary sore-throat, sarcocele, tertiary epilepsy, or specific lung disease; whereas large doses of the drug so marvellously brought into use by Wallace, of Dublin, in 1834, will often effect a rapid and surprising cure.

The rule in practice ought to be that sloughing sore-throat, or ozæna, ought *at once* to be treated by ten-grain doses of iodide of potassium, administered three or four times daily. So, too, with ulcers of the lower extremity and the face, and with phthisis syphilitica.

It seems to me, then, that the indications for mercury in the period of gummy products are few; and that it should only be used when the iodide of potassium has been tried and found wanting. Above all, I think we should never give mercury alone in the tertiary period, as seems to be the fashion at Aix-la-Chapelle. By administering mercury without iodide of potassium, in the tertiary period, we run the risk of seriously compromising the health of the patient, for, whilst inert mercurial treatment is being pursued, the soft or hard palate may be perforated or destroyed. If, then, the practitioner be inclined to give mercury in the period of gummy products, he should at all events combine it with the iodide of potassium. It must be borne in mind that iodide of potassium occasionally, though very rarely, may produce symptoms of acute poisoning. I have sometimes seen eruptions of a formidable nature, vesicles filled with sero-sanguinolent fluid, caused by small doses of that great remedy for syphilis; and once saw a case which apparently proved fatal. In such cases, the disease may be mistaken for syphilis, and more iodide of potassium administered.

Summing up the views contained in the previous pages, I would say at this moment that:—

I. Mercury, in very small doses, should be given in prolonged courses during the first eighteen months of syphilis, leaving off occasionally, and most carefully watching the patient's teeth, etc. This should be done with the view of preventing the occurrence of the tertiary period. Mercury should be given in the period of the hard sore, with the hope of arresting the progress of the disease towards the eruptive stage.

II. When tertiary symptoms appear, they should at once be treated by large doses of the iodide of potassium, combined, in very rare cases, with small doses of the bichloride of mercury. In general, the iodide of potassium is all that is needed to cure tertiary lesions, at any rate temporarily.

MEASURES ADOPTED IN DENMARK TO PREVENT THE SPREAD OF VENEREAL DISEASE.

BY

S. ENGELSTED, M.D.,

PHYSICIAN-IN-CHIEF TO THE COPENHAGEN HOSPITAL.

There existed in early times, in Denmark, a sort of control with respect to loose women, but it seems to have been with a view of rendering them more easily distinguishable from other women, partly by ordering them to wear a certain dress, partly by assigning for them the places they were permitted to live in. Thus, for instance, in the year 1496, King Hans published over all the kingdom, edicts, ordering that common women and harlots should wear, as head-dress, a cap, half red and half black, no stuff better than "Deventyrsk," and no better linen than what might be had at eighteen Skilling an ell.[1]

In a law given by Christian the Second,[2] we find among other things:—

> We will that common loose women living in towns shall not be permitted to live in streets and lanes with other good and honest people, but there shall be assigned to them particular quarters of the towns which they are to inhabit; and We will that they must and shall wear good clothes, etc., such as they can afford and procure; they shall not, however, be permitted to wear mantuas, that they may be distinguished from other, modest women and honest people; and We will that they shall not be molested by blows and wounds. Whoever does such a thing shall have his neck forfeited. If anybody should lose his money, clothes, or other things, by rioting in the houses of such loose women, this shall not be judged by any court. But by this is not understood such women as are on terms only with one fellow. They may live in places convenient for them, such as they please to choose in the town, not, however, in places where there is most and greatest commercial business.

These legal provisions indicate that, in those times, a sort of control existed with respect to public women, and are besides a proof (particularly the latter of them) of a high degree of humanity in promising these women protection against violence and molestation.

In process of time, another way was chosen, and, influenced by the fear of venereal diseases, an attempt was made to counteract the propagation of the same by persecuting women suffering from those diseases. This may be seen, for instance, from a writ issued by Christian the Third in the year 1546, from Aarhus, to all superintendents of the whole kingdom of Denmark,[3] in the following terms:—

> Our love to all. May it be known to all that We have learned from the directors of the common hospitals of the kingdom, that in these hospitals are often admitted women who formerly, when young and healthy, have lived in

[1] J. C. Wendt, History of the Beginning and Progress of Venereal Disease in Denmark, 1820.

[2] Laws given by Christian II., published by Resenius.

[3] J. C. Wendt, op. cit.

notorious profligacy, and led an indecent life, and have thereby been spoiled by *pocks*, *French disease*, and other complaints. We therefore beg and request that you instruct and give orders to all parish priests, in the towns as well as in the country, throughout the whole diocese, that they ever and again, from the pulpit, do proclaim to the common and lower classes of the people, that it has been resolved, that wherever there may be found such loose and spoiled women who, in consequence of their wicked and lewd life, have been spoiled by *pocks* and *French disease*, or other such foul and leprous disease, they shall not, after this day, be admitted to or received at any hospital, there to be supported and nourished, so that everybody may know this, and avoid and abstain from such bad and loose life.

Since that time, several legal provisions and edicts have been published, by which the propagation of venereal diseases has been partly prevented, as far as could be done, by attempts to restrict profligacy. Thus:—

Any male who is found to come to a whore-house to commit fornication, is to be punished; the first time with imprisonment during a week, the second time double the length of time. Females being in such houses, in order to give themselves up to lechery, are to be whipped at the whipping-post, or confined in a house of correction. (Danish Law, 6–13–20.)

Pimps and bawds seducing any man's wife or daughter to live in profligacy and lead a wicked life, are to be whipped at the whipping-post, and driven out of the town by the hangman. (Danish Law, 6–22–1.)

They who keep whore-houses are to be punished by being whipped at the whipping-post, and exiled from the province where they have been living, or confined in the house of correction. (Danish Law, 6–22–5.)

The police-master shall diligently investigate that nothing is publicly done against modesty and decency, and particularly that no whore-houses are kept; and shall do his best that those who keep them, as well as those who frequent them, may be seized and summoned before the police court; and that the brothel-keeper, as well as those who have been found in such houses in order to give themselves up to lewdness, may, after being convicted, be sentenced and punished according to law. (Police Regulations, October 22, 1701. Post II., Chapter 3, § 1.)

They who keep public houses in Copenhagen are forbidden to keep more female servants than are really wanted, or to permit loose women to lodge in their houses, if they will not be sentenced and punished for pimping. (Town-hall placard, July 28, 1828.)

If females are found to stay in houses of bad repute, to stroll about the streets by night, or to have subsisted by idleness, without being able to account for their having a substance sufficient to permit them to live in idleness without hurting anybody; or if such persons, though they have been hale and hearty, have not for a year had any regular service, then they ought to be, the first time, summoned before the police office, there to receive a warning, not only to keep away from such ill-famed houses, but even to take regular service, lawful labour, or have a legal profession; and if, after this, they continue their former life and conduct, he (the police-master) shall sentence and punish them, after the laws, as vagrant persons of no use, but rather hurtful to the public, and send them to work in the house of correction. (Instructions for the Police-master of Copenhagen, March 24, 1741, § 9.)

Besides this, the edict of November 27, 1775, contains several special provisions to prevent lewdness from being practised by women kept by inn-keepers and others for that purpose, and also many directions with regard to the behavior to be observed by such persons with respect to their female servants, and also for the behavior of women out of work with regard to the lower dancing houses, all to the same purpose; and finally, § 9 contains the following:—

Loose and idle women who have their lodgings in separate apartments and rooms, ought, at the request of the police-master, to account for their manner of living; and they are to be punished if complaints are brought forth with respect to the seducing young men, or the like. As to women who trespass against this, the police-master ought, according to circumstances and the peculiarity of the case, and without appeal, to sentence them to pay a fine from two to ten Rbd., or to be punished by detainment, with bread and water, and exposure at the pillory, or to be punished by imprisonment in the rasping-house or "Börnehus," or other house of correction, from one to three months.

Towards the end of the last century a most important provision was issued for preventing the propagation of venereal disease, viz.:—

A Royal Rescript of March 14, 1788, *to the Civil Governor and Bishop of the Diocese of Aarhus, of the following contents:—*

It has been reported to the King that the venereal disease has for a number of years been prevailing in the diocese, and that the chief cause of its continuing is supposed to be that the infected, partly from shame and partly in order to avoid the costs of the cure, conceal the complaint, or apply to quacks, until they suffer most severely from the disease, and spread the contagion. In order to remedy this, it is decreed by these presents that all belonging to the lower classes infected with venereal disease, whether wealthy or poor, shall be favoured with completely free cure, and have the attendance of the surgeon of the district to which they belong; and the surgeon shall have for his pains, from each such patient, a payment of two Rdl.; and all sick persons who, according to trustworthy information to be relied upon, are not rich enough to pay for their being attended while sick, must be treated gratis; and all the expenses of medicine, the doctor's fee and his conveyance, and the support of the poor, are to be paid proportionally after the standard of the land-tax; and the King also wills that the patients from different parishes shall, if possible, be assembled in one town, in order to be cured in the most convenient and shortest way; and that persons of the lower classes, who do not in due time request to be cured, shall, after having been cured, be punished with imprisonment with bread and water, or other arbitrary punishment dictated by the chief magistrate according to circumstances. In the mean time the bishops should duly admonish the clergymen to tell the names of the sick or suspected who are known or may become known to them.

By royal rescript of July 2, 1790, the above rescript was extended to be a rule for the whole kingdom of Denmark. By letter from the ministry of home affairs of December 21, 1863, these rescripts have been interpreted in the most liberal manner possible. This letter was issued in consequence of an inquiry from the Direction of the Infirmary at Aarhus, whether they were obliged to receive venereal patients arriving from other districts, and whether the city of Aarhus was obliged to pay the costs of their stay at the hospital, or whether the costs should be paid by the district where those persons had their home. The jurisdiction of the district admitted that the hospital was in duty bound to receive any syphilitic patient who should ask for admittance, but was of opinion that the costs in such cases, where the persons concerned had their homes in other districts, and had only come or been sent to Aarhus to be received in an hospital to be treated for and cured of syphilis, should be paid by the districts or towns where the persons in question had their homesteads; whereas the costs ought to be paid by the city of Aarhus, if the patient had resided there even for a short time. The ministry agreed with what the district had said, but decided that the costs for cure and support at the hospital should be paid by the district or town where the patient had

his homestead, only when the patient had come to Aarhus in consequence of a summons of the competent authority, in order to be cured there; but not if it were in consequence of his own resolution, or the summons of private people, in which case the general rule was to be applied, that the patient's homestead must pay the cure.

Although prostitution has been acknowledged as a matter of fact, it has not been thought proper, as it has been termed, to legalize it by legal provisions; but it has been tolerated. This tolerance has been looked upon as legal authority in consequence of the police-placard of March 9, 1809, according to which, women belonging to the jurisdiction of Copenhagen were summoned, if suffering from venereal disease, to apply to the police within a fortnight. Persons conforming to this summons were promised free cure and support, and their names kept secret with regard to persons not concerned, and they were free from being accused and punished, even if their conduct had been such that, conformably to the police regulations, they might have been accused of lewdness and idleness; whereas they who did not apply were threatened to be acted against with the whole severity of law. It was in order to avoid, as much as possible, everything that might give to prostitution a stamp of legality, that no formal concessions were given either to public women or to their keepers, and that neither of the parties was to pay for the tolerance shown. The position of public women was not regulated by laws and regulations, but they were under the discretionary authority of the police.

As early as the commencement of this century, *visitation* of public women was introduced at Copenhagen. Between the years 1800 and 1807, the police-master Haagen engaged a physician in order to inspect the prisoners, and to examine public women. By royal rescript of June 6, 1815, which formerly could not be published, the control in Copenhagen was very much improved. This rescript runs as follows:—

To the Police-Director of Copenhagen: We have received a memorial in which has been most humbly proposed to us such means as might be employed against the spreading of syphilitic contagion in our royal residence of Copenhagen, and after having duly considered the matter, we by these presents notify you that, concerning this, we most graciously have established the following stipulations:—

(1) You are authorized to enjoin all who may be looked upon as belonging to the class of trading people, going under the general name of inn-keepers, under pain of punishment according to the law of November 27, 1775, to give up to you their names in full, and the houses they are living in, and when they are about removing, and then at the same time what and how many female servants or lodging females they have at their houses, when and whence they have come, and when they leave their service, and where they are then going; all this for the purpose of procuring for the police an exact knowledge whether any such inn-keeper, under cover of the trade for which he has a license, may intend keeping a whore-house.

(2) You are likewise authorized to demand from loose and idle women who, according to the placard quoted, § 9, ought to account for their mode of living, to let you know their lodgings, and any change of the same, on pain of the above punishment.

(3) You must strictly take care that no women, against decency, try to allure males by indecent gestures or words, in doors or windows, or in the street; and you must sentence women who thus trangress, to punishment according to the placard of November 27, 1775.

(4) To women suspected by the police, and living alone, and to girls living

in public houses that have attracted the suspicion of the police as favoring lewd life, you are to have distributed instructions how to know the venereal disease, which have been printed by the care of our Chancery, and you must induce them to have always these instructions in their houses.

(5) You must order all women named under the foregoing (4) to have themselves visited at their own houses by their own physicians (which physicians ought to be named to you and acknowledged to be skilful), or by the police physician, in places which you must choose; you also must charge them to procure a report from the physician, and this report ought to be delivered at the police office the same day that it has been procured.

(6) You must superintend that the reports of the physicians are punctually delivered, and after that you must have them arranged in such tabular form that they may be easily inspected in order to discover immediately if anybody has neglected to have herself visited, or to deliver her physician's report.

(7) You must give such directions that every one neglecting to deliver such report, shall immediately be visited by the police-physician.

(8) Besides this visitation, which is to take place EVERY MONTH, you must, after deliberation with the town-physician, and at not fixed terms, have such women visited by the police-physician, for the purpose of having a continual control that can be relied on.

(9) As by rescript of this day to the direction of the poor-house of Copenhagen, the same has been charged to have women who are found to be infected, taken to an hospital to be cured, and also to grant to those who ask for it free cure and support there, you are not permitted to allow any woman who is found to be infected, to have herself cured at her house, unless you be assured that this may be done without exposing the public to any danger.

(10) Whenever a woman who is living alone or in a suspected public house, and who, after having received from you the above-mentioned instruction how to know the venereal disease, is by investigation of the police found to be infected to such a degree that she cannot excuse herself by pretending ignorance of the existence of that disease, and has not then applied to be cured, and has in the mean time neglected the visitation ordered by law, she shall not be allowed free cure and support as otherwise given to such patients, but she herself, if she is living alone, or otherwise the inn-keeper at whose house she has been living, shall be ordered to pay the costs of her cure, and in want of payment the costs are to be worked off by public labor.

(11) If any woman or man has been found to have infected a person of the other sex, and the person thus accused is convicted of having known her or himself to be suffering from the disease, and to have nevertheless ventured on incautious intercourse with the other sex, the same is to be punished by the police, with fines or corporal punishment according to circumstances.

By a writ from the Government-office of August 20, 1822, there is repeated what the police-physician has formerly been charged with, and among other things the visitation of public women; but at the commencement of 1841, there had not yet been introduced any definite mode of visitation. When the same was to take place, about once a month (formerly, most likely, four times a year), the public women were summoned, at their lodgings, by the police-officers. In March, 1841, visitation was ordered to take place twice a month; in June, 1844, it was provided to take place once a week; at length, in July, 1853, *twice a week for each woman.* This is now maintained, and the women are no longer summoned at their lodgings to each visitation, but, on a card given to each of them, since 1852, the days are indicated on which they are to appear in order to be examined. Each woman is separately examined with the speculum, and besides the inspection of the exterior genitals and the skin of the thighs and belly, the anus and the cavity of the mouth

are also examined. At every opportunity endeavors are made to detect the persons with whom the women infected with venereal disease have been in contact. Such persons are then, through the police, invited to have themselves visited and duly treated.

With respect to the men of the army and the navy, there are particular provisions with regard to venereal disease. The staff-physician of the navy is, according to instruction of July 10, 1789, § 11, to take care that, among the persons levied for the navy, nobody is suffering from itch, *syphilitic exanthemata*, ulcers on the legs, ruptures, etc. Whenever a vessel is to put to sea, a visitation is ordered to take place.

With respect to the army, a writ from the ministry of war (College of General Commissariat) dated May 5, 1804, orders that the men shall be visited before they are sent home, in order to prevent their bringing venereal disease to their respective communities. If they are found to be suffering from such disease, they are detained in their garrison until the competent chief-physician can give them a certificate of health. A circular of August 5, 1805, from the same board, provides that, at the beginning of their time of service, an instruction shall be given to the soldiers respecting the symptoms of the disease, that they may know the dangers connected with their concealing or neglecting the same. All sergeants, musicians, and soldiers are visited when beginning their time of service, when being dismissed, and as a rule regularly twice a month. In order to prevent, as far as possible, the propagation of syphilis in the cities, military persons suffering from that disease are required to indicate the probable source of their disease, so that the police may know it, and prevent such woman from further propagating the disease.

The measures taken to prevent the propagation of venereal contagion have been, as may be seen from the preceding notices, arbitrary, and consequently not sufficiently to be relied on. This has been remedied by the following:—

Law of April 10, 1874, *respecting Measures to prevent the Propagation of Venereal Disease* (*approved by the Parliament and by the King*):—

§ 1. Persons suffering from venereal disease, whether able or not to defray their cure, are entitled to claim medical attendance at public expense, and in the mean time they are bound to submit to such cure if they cannot prove their having private medical attendance; if the circumstances of the persons affected are such that the contagion from them to other persons can be satisfactorily prevented only by their removal, or if they do not observe the instructions given in order to prevent contagion, they must be taken to an hospital to be cured. Respective questions are, if necessary, to be decided by the bailiff (in Copenhagen by the director of police) under recourse to the minister of justice; and the observance of the obligation can be enforced by coercive fines, dictated by the authorities. Persons who receive support through regular public alms and are found to be suffering from venereal disease, must be taken to an hospital to be cured. If, after the disease being cured, there is a particular reason to fear relapse of the same in a contagious form, the physician who has attended the patient may give her the injunction to appear before him at a fixed time, or to produce a certificate from an authorized physician that no such relapse has taken place. This injunction may also be enforced by coercive fines, dictated by the above-mentioned authorities.

§ 2. A child suffering from venereal disease must not be given to be suckled by any other woman than its own mother, nor is any nurse knowing or supposing herself to be suffering from the disease, permitted to take the child of any other mother to suckle it. Respective transgressions incur the penalty

mentioned for the crime in question, in § 181 of the General Civil Penal Law, and in the mean time the transgressor, if the disease has been propagated, shall be bound not only to indemnify the infected persons for the expenses connected with their cure, but also to give indemnity for the sufferings and losses occasioned by the disease. The same duty of indemnification is incumbent on any person who places a child at nurse, knowing that it is suffering from venereal disease, or suspecting it to be so, or who gives a child, suspected of the disease, to be suckled, without previously informing the foster-parents or the nurse that the child is suffering or suspected. These legal provisions are also applicable to public authorities who place children to be fostered or suckled. A child is to be looked upon as suspected of suffering from the above-mentioned disease, even if no symptoms of it have been observed, if the mother is suffering or has formerly suffered from the disease in any of its constitutional forms, and three months have not elapsed since the birth.

§ 3. If a woman, not belonging to those who, by regulations or rules, are submitted to the inspection of the police as belonging to prostitution, is definitively suspected of subsisting by prostitution, she is to receive warnings from the police, and to be informed of the consequences connected with the neglect of the warnings. In the mean time, if she consents to it, or admits herself to be leading a licentious life, she is to be examined by a physician, and, if she is found to suffer from venereal disease, to be submitted to cure according to § 1. A woman duly taught and authorized can also be trusted with this examination, and in that case the consent alluded to will not be necessary.

§ 4. § 180 of the Penal Law has been changed in such a manner that the penalty of imprisonment mentioned in the same may, where no compulsory workhouses exist as appointed by law for expiating punishment for vagrancies, be changed to compulsory work for a period not exceeding ninety days. If a woman is accused so as to be punished according to § 180 of the Penal Law, she is to be examined by a physician, and, if she is found to be suffering from venereal disease, is to be submitted to cure according to § 1. After having suffered the punishment, she is again to be warned according to § 3, and may then be submitted to the inspection of the police, conformably to the rules given in the following paragraphs.

§ 5. If a woman, in consequence of the preceding paragraph, is submitted to the inspection of the police, or voluntarily submits to it, she is to be ordered by the police to submit to medical examination at fixed periods, and to give notice of every change of lodgings. If, when examined by a physician, she is found to be suffering from venereal disease, she is to be submitted to cure according to § 1.

§ 6. Transgressions of the injunctions given in consequence of the preceding paragraph, are punished by imprisonment with bread and water for a period not exceeding four days, imprisonment with the usual prison-fare not exceeding sixteen days, or compulsory labor not exceeding twenty-four days (compare § 4.) If such woman does not present herself to be examined, and has no admissible reason for her absence, and is afterwards found to be suffering from venereal disease, she may, if residing at Copenhagen, or any other place having, in consequence of the law of February 4, 1871, § 2, Libra C., legal provisions for the inspection of licentious women, by the decision of the respective police masters, be submitted to the rules and regulations of that place respecting the inspection of licentious women. But she cannot be ordered to live in public houses unless her conduct after that time necessitates such measures.

§ 7. A woman who has already been sentenced according to § 180 of the Penal Law (compare § 4 of this law), and who is again found to have been guilty of subsisting by prostitution, is, besides being punished in consequence of the said rules, with the restriction mentioned in the preceding § 6, to be submitted to the regulations or rules for the inspection of licentious women, as long as, after having suffered the punishment, she continues to sojourn at

Copenhagen, or any other place for which, in consequence of the law of February 4, 1871, § 2, Libra C., such rules are given.

§ 8. The inspection mentioned in § 5 ceases, as far as the woman in question has not already formerly, in consequence of §§ 6 and 7, been submitted to, or has herself submitted to, the inspection which according to regulations and rules is instituted in certain places for licentious women, at all events at the expiration of six months. If, with respect to a woman's situation or conduct, such change has taken place as may be considered sufficient security with respect to her future conduct, the police master ought to exempt her from inspection before the expiration of the period mentioned.

§ 9. The medical examinations mentioned in this law are, if at the place in question no local police-physician has been appointed, to be executed by the public physician of the place, and in the locality designated by the police. For this the physician receives an annual remuneration, fixed by the municipality and approved by the minister of justice, or, if such remuneration has not been fixed and approved, a payment, for each examination, of 4 Kroner (2 Rd.) for the first person examined at the same time and at the same place, and 1 Kroner (48 Skilling) for each following person. The remuneration is paid from the town fund, in the country from the fund of repartition of the district, and in Bornholm from the united fund of town and district. The physician is not separately paid for a certificate stating whether the person examined has been found or not found to be suffering from the disease. The medical examination mentioned in §§ 3 and 5 may also, with the permission of the police-master, and on condition that the particular regulations given are observed, be executed by an authorized physician approved by the police, with whom the woman in question must then herself settle the matter.

§ 10. They who at public expense are taken to an hospital to be treated for venereal disease, are not permitted to leave the hospital before they have been dismissed by the physician of the hospital. Transgressions of this rule are punished by imprisonment with bread and water not exceeding five days, or simple imprisonment not exceeding one month.

§ 11. Lawsuits in consequence of §§ 4, 6, and 10 of this law are prosecuted in the same manner as public cases, but at Copenhagen with closed doors. The police is authorized to forbid persons, keeping public houses, to lodge women who have received warnings according to § 3 of this law, and also to forbid them to employ such women for the entertainment of their guests, or as servants.

If women submitted to the inspection of the police or subsisting by prostitution, or persons assisting and lodging them, are guilty of transgressions or neglect of the above prohibition with respect to regulations or rules which, in consequence of law of February 11, 1863, § 8, or law of February 4, 1871, § 2, C., are given for the inspection of licentious women, the police-master is authorized to sentence such persons to a fine not exceeding 100 Kroner (50 rix-dollars), imprisonment with bread and water not exceeding four days, or imprisonment with the usual prison-fare not exceeding sixteen days, or compulsory labor not exceeding twenty-four days.

Full effect was afterwards secured to this law by the police, through a practical provision. It being well known that a great number of the women who, in the capital, were comprehended in the above law came from other jurisdictions, and that, on the other hand, women who in the capital had received warnings according to § 180 of the Penal Law, or who had been entered in the registers of public women, left the capital and went to the provinces in order to continue a licentious life there, it was attempted to bring about a control based on a regular co-operation between the police of Copenhagen and that of the rest of the kingdom, with respect to such women during their removal to different parts of the country. It was stipulated by the police of Copenhagen that, when-

ever a woman under inspection as mentioned in § 5, or at length entered in the registers for public women, gave notice that she would leave the town, or was known by the police to go to another part of the kingdom, the respective police authorities should be informed of it; from such authorities the police of Copenhagen then requested similar communications, and to be informed of every sentence passed against any woman for transgressions after having received warnings according to § 180 of the Penal Law. In an appendix to the Police-Intelligence, published on the first and fifteenth of every month, and sent to all the police authorities, informations are given *partly* with regard to Copenhagen, respecting all women under inspection, or having left inspection, or entered in the registers for public women and again crossed out, *partly* with regard to the whole kingdom, respecting women who have been sentenced for transgressions after warnings according to § 180 of the Penal Law.

The warning mentioned in the law is by the police of Copenhagen given to the respective women by means of a printed blank, as follows:—

Transcript from the Registers of Warnings, kept by the Police of Copenhagen, for licentious women.

Case No. . . .

Year 18 . . the . . . has been given to . . . . . . the following warning: born at . . . . . . years old, and now lodging at . . . . . having admitted herself to have incurred positive suspicion of subsisting by prostitution, warning is given to her according to § 3 of law of April 10, 1874, and she has been given to understand that a transgression of the warning, according to § 180 of the Penal Law, and § 4 of the law above mentioned, will entail upon her punishment of imprisonment or compulsory labor.

For the correctness of the transcript:

. . . . , Police Inspector.

Women who, according to law, are submitted to the inspection of the police, receive a printed blank of the following contents:—

Transcript from the Registers of Warnings, kept by the Police of Copenhagen, for licentious women.

Year 18 . . the . . . . . . , who, according to sentence passed by the criminal and police court, division for public police cases, has suffered punishment of . . . . . . for transgression against § 180 of the Penal Law, appeared, and received renewed warning conformably to the warning given to her the . . . and which was read to her, and she was given to understand that a transgression would entail upon her punishment of imprisonment or compulsory labor.

It was at the same time declared to her that, according to § 4 of the law of April 10, 1874, she was submitted to the inspection of the police, and she was, therefore, given the injunction to appear, for the purpose of medical examination, in that division every . . . day, between . . . . and . . . . o'clock in the afternoon, and to give notice of any change of lodgings within twenty-four hours, under penalty of punishment according to the said paragraph, if she should in any way transgress against this injunction.

For the correctness of the transcript:

. . . . , Police Inspector.

On this transcript are also printed the contents of the penal law, and an extract from the law of April 10, 1874. Public women entered in the registers according to the law of April 10, 1874, have been, since that time, according to § 8 of the law of February 11, 1863, subjected to treatment according to the following regulations:—

Regulations for the Inspection of the Police respecting public women in Copenhagen.

By whom the inspection is to be made.—§ 1. The inspection incumbent on the police with respect to public women, is to be made conformably to § 31 of police instructions of June 7, 1869, by the third police inspector, and under the superintendence of the police director. The increase of medical assistance required in consequence of the execution of the sanitary measures connected with the said inspection, and also the distribution of the medical functions, is, according to § 7 of the law concerning the re-arrangement of the police of Copenhagen, to be regulated by supplements to the police regulations of June 12 of last year [1873], and to the police instructions of June 7, 1869.

Public Women.—§ 2. Every woman registered as a public woman is subjected to these regulations, and to the right of punishing which the police director has been given by the law respecting the mode of treatment of public police cases, of February 11, 1863, § 3. (Compare law of April 10, 1874, § 12.)

§ 3. No woman can, at her own request, be registered among public women before she has completed her eighteenth year. Exceptions, however, may be made with regard to women who are well known to have already become addicted to a licentious life, and when all endeavors to reform them have proved fruitless, and if they have, at the same time, completed their sixteenth year, and are of sufficient bodily development.

§ 4. No married woman can, at her own request, be registered as a public woman, unless she has been abandoned by her husband; and the latter, if his declaration in this respect is to be had, refuses to renew cohabitation.

§ 5. With regard to every woman, registered as a public woman, exact information must be produced of her name in full, place of birth, age, homestead and last place of residence, her own personal situation and preceding life, together with her motives for this step. It is therefore the duty of the police inspector, whenever a woman requests to be registered as a public woman, and especially if she has not already been submitted to the inspection mentioned in §§ 3–7 of the law for measures to prevent the propagation of venereal diseases, to satisfy himself that such woman fully knows the import and consequences of her intention, and by admonitions, by the assistance of her relations, and by other means at his disposal, to try to induce her to better purposes, and, if possible, facilitate her return to decent life.

§ 6. If, after the above injunctions having been observed, it is found that her request ought to be granted, she is to be submitted to medical examination, in order to ascertain whether her bodily constitution should in any way prevent her from being registered, and whether she is at the time free from venereal contagion. She is afterwards, by the police inspector, and before the protocol, to be acquainted with all the contents of these regulations, the needful of which is to be entered in the registers, and after this read to her, in the presence of valid witnesses, and agreed upon and signed by her. She is then registered in the list of public women which is to be kept in schematical form, containing, for each woman, an extract of notices concerning her person.

§ 7. When inscribed, such a woman receives, against a certain payment, a control-book containing the paragraphs of the present regulations with regard to her position as a public woman, as well as other rules that are to be observed by her, together with rubrics for medical visitations during a whole year. On the title-page is written her name in full, and the day when inscribed; on the next page the days on which she is to present herself for medical examination together with subsequent changes in that respect, and on the last page of the book her lodgings, and, if she is living in a public house, also the number of her room, together with later changes in this respect.

§ 8. Public women, with the exceptions afterwards mentioned in §§ 15 and 49, ought always to be in the possession of their books of control, in order to be able to produce them whenever so requested by the police. It is strongly

forbidden to pawn them, or to lend them to others. If a pubiic woman has lost her book of control, she ought, immediately, to inform the third inspector of it, when a new copy, marked "renewed," is to be given to her.

§ 9. The public women are divided in two classes: (1) Women who are living by themselves; (2) women living in public houses. To the first class belong: (*a*) those inscribed in consequence of §§ 6 and 7 of the law of April 10, 1874, as long as their conduct does not necessitate their being ordered to take lodgings in a public house; (*b*) those who have special permission to live by themselves. Such permission can be given by the police inspector, but, as a rule, only to those women whose conduct has always been unexceptionable, and only with the consent of the landlord of the house. This permission may be recalled at any time, and this ought to be done with such women as are often guilty of transgressions of these present regulations, particularly of §§ 11 and 12. All other women must live in public houses.

§ 10. Every public woman, whether living in a public house or by herself, must have the permission of the police inspector to change her lodgings, and, if she is herself the cause of her removing, she is only permitted to remove twice a month.

§ 11. No public woman is permitted to have her child at her house after its fourth year, and by no means the children of other people. She is not permitted to have her sweetheart at her house. She is not permitted to receive visits from males who are not yet adult. She is not allowed to receive any pawn from males visiting her. She is not allowed to lodge other women. The police has free access to inspect her rooms by day and night.

§ 12. Public women must carefully abstain from any disorder and from any indecent behavior in streets and public places, and must strictly observe the rules given them by the police in that respect; especially are they forbidden: (1) To appear in any indecent or sensational dress; (2) to show any indecent behavior; (3) to flock, to follow anybody, to accost or call anybody by words or signs; (4) to place themselves at their windows, or to be standing in the house-door, in the street, or on the foot-pavement before their houses; (5) to go in company with several others, or to marshal up, or walk up and down streets, public places, and walks; (6) to have other places in the theatres or public places of amusement than those permitted by the police; and (7) to be sitting guests in coffee houses, restaurants, and similar places of entertainment. During the time that the street lamps are lit, the regulations given under (4) need not be observed by public women living in the following streets: Holmensgade between Lille Kongensgade and Vingaardstræde, Bróndstroderne, and Diderik Badskjorsgang. Public women are never allowed to go through Amaliegaderne and Amalienberg Plads, nor, after particular orders from the police, in the principal streets of the city later than noon. Public women living in public houses are not permitted to appear in the street from the time when the street-lamps are lit, until they have been put out; the police-director is authorized to allow exceptions from this injunction.

§ 13. Public women are strongly forbidden to apply to males who have visited them, or to the relations of the same, in order to ask money from them, or for other reasons. But they may request, and according to circumstances expect, the intervention of the police.

§ 14. No public woman is permitted to go beyond the limits of the jurisdictions of the northern and southern parts of the district of Copenhagen and the jurisdiction of the island of Amager, nor to be absent more than twenty-four hours. Before being permitted to undertake a journey, she is to be visited by a physician.

§ 15. As soon as any public woman thinks herself infected with venereal disease, she ought to apply immediately to the examining physician, or to present herself at the hospital kept for that disease, and there she must deliver her control-book, that it may be sent to the police-inspector together with information respecting her being admitted at the hospital. Every public

woman admitted at an hospital for any other complaint than venereal disease, must also deliver her control-book at the hospital.

§ 16. Whenever a public woman is by illness prevented from coming to the medical inspection, she must every day of the usual examination send to the police-inspector an attestation from the physician attending her, concerning the nature of her illness, and that there is no symptom of venereal disease, or else apply for the inspector's permission to be examined at her home.

§ 17. Whenever a public woman, by certificate of marriage, has proved that she has been legally married, she is to be immediately obliterated from the registers of inscription.

§ 18. A public woman otherwise wishing to be obliterated from the registers of inscription, ought to apply to the police-inspector, whom she is to make fully acquainted with her future profession, occupation, and lodging, and who is then to inform the police-director of the case, and he is then to decide whether her request can be complied with; she must, however, if she does not adopt a solid position of life, or may by other means come to a situation offering sufficient security as to her future conduct, continue to be under the inspection of the police, and be subjected to the right of punishing with which the police-director is invested according to § 12 of the law of April 10, 1874, until, after having shown an unexceptionable conduct during three months, she may be definitively obliterated.

§ 19. Every woman obliterated from the registers of inscription, ought to receive a warning conformably to § 180 of the Penal Law, and it ought to be said to her that, if she again tries to subsist by prostitution, she will be prosecuted and punished, and submitted to the measures ordered by §§ 4–7 of the law of April 10, 1874, and, among other things, be immediately entered in the registers as a public woman if she has formerly been punished for licentious life.

§ 20. *Public Houses.*—The police is authorized to allow the existence of houses to afford lodgings for public women, under the inspection and responsibility of a hostess living in the house. Such concession may exceptionally be given to male persons, who are then subjected to the same regulations given, in the following sections, for the hostess.

§ 21. Concession to keep a public house is given by the police-director. It is always granted for an undetermined period, and preferably to old public women whose conduct has been without grievances. When such concession is sought for, the house must be exactly described, and it must be proved that the house-owner's consent has been given.

§ 22. Such public houses can, without the consent of the magistracy, only be permitted in the following streets: Lille Bróndstrode, Diderik Badskjorsgang, Dybensgade, Faruergade, Gaasegade, Helsingorsgade, Holmensgade (between Lille Kongensgade and Vingaardsstrode), Hummergade, Knabrostrode, Magstrode, St. Gertrudstode, Tornebuskegade, and Vogumagergade. A street once having become free from such public houses, new ones cannot be established there without the consent of the magistracy.

§ 23. Every hostess keeping a public house, shall be submitted to the present regulations, and the right of punishing given to the police-director by § 3 of the law of February 11, 1863. She must also conform to the injunctions which the police may find it necessary to give her.

§ 24. No married woman, dependent on her husband, can be permitted to establish a public house, without the written consent of her husband.

§ 25. In a public house no other inmates are permitted, without the permission of the police-director, but only the hostess, her husband, and children under the age of 7 years, the public women, and the necessary female servants. All rooms for public women ought to have consecutive numbers on the outside and the inside of the door, written in plain figures.

§ 26. They who keep public houses are bound to observe the greatest possible cleanliness, and to procure all such things as the police-director, after

having discussed the matter with the examining physician, may prescribe with respect to health. The windows facing the streets must always have Venetian blinds that are locked up.

§ 27. The hostesses of public houses must be accountable for the lodging women's coming to medical examination at the fixed hours, and in clean and decent dress.

§ 28. They who keep public houses cannot by any means refuse to the police officers to inspect the house, by day or by night.

§ 29. They are not permitted to give lodgings to any public woman, without notifying it to the police. The police-inspector must fix the number of public women allowed to each house.

§ 30. The hostesses of public houses are bound to inform the police-inspector of the name, age, and native place of each of their servants, and the latter can only be engaged with the consent of the police-inspector. Hostesses who are unmarried, or separated or divorced from their husbands, can be submitted to medical examination as ordered by §§ 40–49 and 52–54.

§ 31. The police is authorized to fix the payment which the woman living in public houses must pay both for room and fare in the house, and the hostess is to conform to this injunction.

§ 32. The hostess is answerable for the observance of the injunctions given in § 11, and she also can be rendered answerable that public women living at her house observe the injunctions of § 12, as far as, according to the nature of the same, she is able to have any influence in that respect.

§ 33. When a public woman has been given notice from her hostess to remove, both of them must, at the same time, appear before the third police-inspector, in order to have the necessary remarks added to the registers of inscription, and in the woman's book. Removal may be notified from both sides, with only twenty-four hours' notice.

§ 34. The hostesses are subject to punishment if women are found in their houses who have not their books of control, and have not given notice that they have been lost, or who have not been duly announced to the police conformably to § 29.

§ 35. The hostesses of public houses must always have in their possession an extract from these present regulations, containing all injunctions with regard to them; it must be bound like a book, and must bear the name of the hostess and the street number of the house, and state the number of public women permitted to live there.

§ 36. Any dissension taking place between the hostess and the public women living at her house, concerning their situation in that quality, is to be decided by the third police-inspector, and may only by his permission, or that of the police-director, be brought before a tribunal.

§ 37. All sorts of games with the guests are forbidden in the public houses.

§ 38. Objects having been forgotten in such houses ought to be delivered to the police within twenty-four hours.

§ 39. The hostesses are not permitted to leave the town for more than one day.

Sanitary measures.—§ 40. Every public woman ought to be, as a rule, submitted to ordinary medical examination twice a week.

§ 41. Extraordinary medical examinations are to take place as often as the police-officer thinks it necessary, and they do not exempt the public women from the ordinary medical examinations.

§ 42. The ordinary medical examinations are made in the public localities kept for that purpose; and there must be at least two such rooms in convenient parts of the town, besides the rooms for examinations at the police office. Medical examinations may also be allowed to take place at home, where the localities are fit for such use. This permission is granted by the police-director with respect to public houses, but may be given by the police-inspector to women that have private lodgings. The police-inspector is also

authorized to permit a woman who has private lodgings, to have her own physician, approved by him, whose certificate that she is not suffering from any venereal disease then replaces the medical examination. Such permissions may be recalled at any time.

§ 43. Public women who do not appear to be medically examined, or who are not at home in their houses at the time fixed for their examination, are to be arrested and taken to the police office to be examined, and are also subject to punishment.

§ 44. If any public woman tries to prevent the examination from being made as exactly as the physician thinks necessary, she is looked upon as having not appeared; and, according to circumstances, can also be taken to an hospital for observation.

§ 45. Whenever an ordinary or extraordinary examination has taken place, the physician is to inscribe in the control-books of the public women, and in registers kept for that purpose, the day when the medical examination took place, the state of health of the woman, the nature of the complaints observed, and other remarks he thinks useful. All these remarks ought to be made by the examining physician in person.

§ 46. Every public woman who by ordinary or extraordinary examination is found to be suffering from venereal disease, is to be taken immediately to an hospital, and have along with her a certificate declaring the nature of the complaint and where it is. Persons who show dubious symptoms of this disease are likewise taken to an hospital until it has been decided whether they are infected or not. In consequence thereof, women who are living alone, and are permitted to be examined at home, must appear at the hospital if they have not been found to be sound; and the hostesses of public houses who are allowed to have the examinations made in their houses, are co-responsible that persons living in their houses, and who at the medical examination are found to be infected or are suspected of being so, are immediately sent to the hospital.

§ 47. Every conveyance of loose women between the police office and the hospitals must be by carriage, and, as far as possible, at the cost of the respective women.

§ 48. Any public woman who, after having been declared to be suffering from venereal disease, removes from her lodgings, is immediately to be apprehended and carried to the hospital, and, after being cured, is to be punished. Likewise every public woman who is found to be suffering from the said disease without having declared it, will be punished if, according to the declaration of the physician, it must be supposed that, in consequence of the nature of the disease, she cannot possibly have been ignorant of it. Every public woman who is conscious of, or supposes herself to be afflicted with, venereal disease, and has nevertheless sexual intercourse, will be prosecuted and punished according to § 181 of the Penal Law.

§ 49. Whilst public women are at the hospital, their control-books are deposited at the police office, and are only returned to them when they have been dismissed from the hospital after having been cured. They are also, during the rest of their stay at the hospital, subjected to the injunctions of the police with respect to their conduct, and submitted to the right of punishing.

§ 50. Public women are bound to observe strictly the sanitary rules given to them by the examining physicians, or the police-inspector, or the physicians of the respective hospitals.

§ 51. The examining physicians are not permitted to treat public women, their hostesses, or the servants of the hostesses, for venereal disease or any other illness, nor to receive any fee from them or from others on their account.

Payment for medical examinations, etc. — § 52. Extraordinary medical examinations shall not be paid for. Likewise the ordinary medical examination, in at least one of the public localities for examination, is to be made gratis. For other ordinary examinations, when executed in the public rooms for examination, must be paid 25 Ore, or 50 Ore for each separate examination

after the time when they ought to have taken place; and, when executed at home, 1 Krone if the examination is executed in a public house, and 1 Kr. 50 Öre when in private lodgings.

§ 53. The fee for examinations at home, as well as for examinations to be paid for in public rooms for examinations, is to be paid in advance for a fortnight to the third police-inspector, and, as to examinations in public houses, paid by the respective hostesses or hosts, or else by the respective women. The hostess or the woman is given a mark for each examination paid for in advance, when the examination takes place, given to the physician and by him to be delivered to the police-inspector.

§ 54. Every public woman who has not paid in advance, and, according to the above rules, in due time, is in consequence thereof bound to appear at the next medical examination (§ 7) in the rooms for examinations gratis, and at the time fixed for such examinations.

§ 55. The control-books for the public women, as well as the books, etc., which, according to these regulations, must be found in public houses, are furnished by the police, but are paid for by the respective women or hostesses with a price like that which the police has paid for them.

Divers provisions.—§ 56. Public women subjected to these regulations who, without the precincts of the town, are guilty of transgressions against the obligations under which they are, according to these regulations or in consequence of the same, are to be punished as if the transgressions had taken place within the precincts of the town.

§ 57. The police-director is, by § 12 of the law of April 10, 1874, authorized to dictate punishment by fines not exceeding 100 Kr., imprisonment with bread and water not exceeding four days, and imprisonment with the usual prison-fare not exceeding sixteen days, or compulsory labor in the institution for compulsory labor at Copenhagen, to public women, hostesses (and hosts) who have a concession to keep public houses, and to the servants whom the police-inspector has permitted the hostesses or public women to have.

§ 58. All expenses occasioned by the inspection of public women are to be paid by the municipal fund which receives the payment fixed by § 52 for medical examinations.

Similar regulations may, according to § 2, C., of the law of February 4, 1871, be made for country towns.

No positive results of the law of April 10, 1874, can, of course, yet be pointed out with respect to the diminution of the venereal diseases; but such effects can be stated as will give an idea of the results that may be hoped for.

No greater number of public women has been registered than formerly. The respective yearly numbers were

1872	289
1873	294
1874	353
1875	345

but before that time the numbers were as large; thus in

1862	354
1863	352
1864	354

and for the rest it has been between 200 and 300. But the number of women under control, by being submitted to medical inspection without being registered as public women, has risen to a very high degree. The number of women suspected of a licentious life, and who have produced attestations from private physicians, are

1872	337
1873	567
1874	1027
1875	1340

These numbers show that, since 1874, control has been effected with a very great number of the sort of women who are the most dangerous with respect to the propagation of venereal contagion.[1] The great importance of this control may be seen from the following table, in which the first columns refer to the women under inspection, and the others to women not under frequent inspection, but occasionally apprehended and examined by the police.

Result of examinations of women under inspection.		Result of examinations of women not under inspection.

[1] Among special affections I will only mention mucous patches, which have been found nine times as often in women not under control as in those registered and regularly inspected.

SECTION ON OBSTETRICS.

PRESIDENT OF THE SECTION.

ROBERT BARNES, M.D.,
OF LONDON.

VICE-PRESIDENTS.

ALEXANDER R. SIMPSON, M.D.,
OF EDINBURGH.

WILLIAM H. BYFORD, M.D.,
OF CHICAGO.

SECRETARY.

WILLIAM GOODELL, M.D.,
OF PHILADELPHIA.

On taking the chair, Dr. BARNES said:—

I do not know how I can express my thanks for the very unexpected honor of being called upon to preside over this Section—one of the most important connected with this Congress. In England we recognize the value of this branch of study, but there is no country that can claim superiority over America in the development of the science of Obstetrics. Your writers are acknowledged as authorities, and, as you are in the lead, it is incumbent upon you to cultivate and improve your discoveries. It is incumbent upon us all to cultivate the practice of obstetrics, for it lies at the very root of the human race. I have been asked why I did not attend a congress in St. Petersburg, which may be called a great medical centre. I preferred to come here, and yet it seems singular to leave the centre and come to what we might call the outside. It is no slight task to spend three weeks of one's holiday on the stormy ocean, but our assembly to-day is an event—it might be called an epoch—in the History of Medicine. I cannot sufficiently express my sense of the honor conferred upon me. I hope to hear some interesting discussions upon the topics brought before us, and have no doubt that I shall go back to my home wiser than when I came.

THE CAUSES AND TREATMENT OF NON-PUERPERAL HEMORRHAGES OF THE WOMB.

BY
WILLIAM H. BYFORD, M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN IN THE CHICAGO MEDICAL COLLEGE.

The short time at my disposal makes it impossible for me to give anything more than a brief outline of the etiology and therapeutics of uterine hemorrhage, and I shall, therefore, confine myself to a succinct expression of the views which may be fairly sustained by our present knowledge of the subject.

Without stopping to discuss at length the meaning of the terms applied to uterine hemorrhages, I may say that I shall use the words "uterine hemorrhage" and "metrorrhagia" in the same sense, and shall apply them to such losses of blood as occur between the menstrual periods, or in unusual amounts at the time of the periods themselves. An excessive, or too long-continued, flow of blood at a menstrual period is practically neither more nor less than metrorrhagia, originating in like causes, and amenable to the same treatment.

Causes of Metrorrhagia.

Non-puerperal hemorrhage is properly regarded as a symptom, and the consideration of its causes brings to our attention a great variety of local and general pathological conditions. Exceptional cases of metrorrhagia sometimes result from direct violence to the uterus, or from sudden and severe shocks to the system, which apparently act upon the uterus in common with other organs, and cause it to bleed because of its inherent tendency to do so. The pathological causes which induce uterine hemorrhage do not always—perhaps do not generally—act singly, but two or more of them are found associated in most cases, some being essential, and others merely auxiliary. The uterus, by virtue of the conditions upon which menstruation depends, is naturally a hemorrhagic organ; and it is in consequence of its anatomical and physiological peculiarities that the ordinary and frequently acting causes of uterine hemorrhage are rendered so potent and effective.

The more obvious phenomena of menstruation are doubtless the result of a definite reflex nervous influence exerted by the ovaries upon the uterus. Although this influence is more distinctly manifested in the great hyperæmia which precedes the occurrence of the catamenial discharge, and the changes in the utricular glands and mucous membrane of the womb, yet it is unquestionably constant in its action and parallel in this respect to that which presides over the motions of the heart, the arteries, and the alimentary canal. Generated in the nervous apparatus of the ovaries, and contemporaneous with the changes called ovulation in those organs, this influence is probably conveyed by afferent nerves to the genito-spinal centre (the existence of which was first established by

Budge, of Greifswalde[1]), or to some other reflecting ganglion, whence it is sent back to the uterus, giving rise to a wonderful series of tissue-changes during the month. Some of these changes have been lucidly described by Dr. John Williams, in the Obstetrical Journal of Great Britain and Ireland, and by our own talented young countryman, Dr. Engelman, in his recent essay upon the subject, published in the American Journal of Obstetrics. These changes are aptly termed by Aveling, nidation and denidation.

A few days before the menstrual flow makes its appearance, the whole uterus, and especially its mucous membrane, becomes greatly hypertrophied and very vascular; when the discharge begins, the membrane is invaded by fatty degeneration. This process is so rapid that, in four or five days, the entire mucous membrane disappears, leaving the muscular structure of the inside of the uterus exposed, while some remnants of the utricular glands are left, and found entangled among the denuded fibres. As soon as the monthly flow ceases, a reproduction of the membrane is commenced, and it continues to grow until at the end of twenty-eight days its menstrual maturity is attained. Accompanying these changes in the cavity of the uterus are others equally remarkable, affecting all the other tissues of the organ. The bloodvessels become enlarged, and circulate an increased amount of blood; the fibrous tissue is developed beyond its inter-menstrual condition; while hyperæsthesia indicates extraordinary nervous endowment. In fact a true hypertrophy of the uterus occurs. During the discharge, the process of involution reduces the organ to its smallest dimensions, and the hemorrhage ceases. The culmination of this hypertrophy in the discharge of blood from the uterus is doubtless not merely an accompaniment, but a consequence of the breach of capillaries in the mucous membrane. These of course are physiological phenomena, but I desire to invite attention to the fact that they strongly resemble pathological conditions, and would be so considered in any other organ in the human economy. Moreover the dividing line between health and disease in uterine hemorrhage is as difficult to trace as that between sanity and lunacy.

It is not difficult to understand that an exaggeration of the hyperæmia, or an unusually rapid disintegration of the uterine mucous membrane, would cause more than a normal amount of flow; nor that a want of accordance in time might be followed by the same result. Indeed most cases of uterine hemorrhage are traceable to conditions which disturb the equilibrium of these phenomena. The causes which thus act are varied and numerous.

Morbid nervous influences which increase the discharge of blood from the uterus, sometimes emanate from the nervous centres, and hence may be properly termed *centric;* much more frequently, however, they are reflected through the nervous centres from other and sometimes distant organs, and these last are entitled to the denomination of *reflex* or *eccentric* nervous influences.

Mental and emotional excitement emanating directly from the brain, and cerebral and spinal excitement originating in inflammation or functional exhaustion of the brain or spinal cord, are examples of *centric* etiological influences. Many years ago I witnessed the ravages of an

[1] Ueber das Centrum genito-spinales des N. sympatheticus. Virchow's Archiv f. Path. Anat. und Klin. Med., Band XV., S. 115–126, and Chicago Journal of Nervous and Mental Diseases.

epidemic of cerebro-spinal inflammation, in which uterine hemorrhage was of almost universal occurrence among those adult females who fell under its influence.

Morbid *reflex* nervous influences afford a more numerous class of causes. First among them, both in frequency and importance, are those arising from abnormal conditions of the ovaries, such as congestion, inflammation, displacement, and erotic excitement. Next to the influence of these bodies is that exerted by the mammary glands. Menstruation is generally more profuse when it occurs during lactation. The effect of mammary irritation in causing congestion of the uterus, and thus promoting hemorrhage from it, is well illustrated by the familiar fact that sinapisms or blisters applied to the breasts will often cause metrorrhagia. Vesical irritation or inflammation, which gives rise to tenesmus; rectal irritation, as from the presence of hemorrhoids, or ascarides; and dysenteric inflammation, through the reflex influence which they exert upon the uterus, are generally recognized causes of uterine hemorrhage. Among other reflex causes may be mentioned certain forms of indigestion, hepatic congestion and inflammation, and some of the disturbances of the small intestines, as may also strong impressions upon the cutaneous surface, as from cold, or from the long-continued application of heat in warm climates and seasons.

All of these last-mentioned causes I think act through the reflex system of spinal nerves, and perhaps also through the agency of the sympathetic ganglia which perform a reflex function between the viscera. The morbid effects of the various reflex nervous impressions are rendered more effective and intense by the presence of such uterine diseases as predispose to hemorrhage by increasing the vascularity of the uterus.

Many *pathological conditions* which conduce to the production of uterine hemorrhage, independently of direct nervous influence, act by increasing the hyperæmia of the uterus. When the mucous membrane is granulated, or is the seat of inflammation, of fibrous polypus, or of malignant fungus, the circulation of the uterus is increased, and harmony in the process of nidation disturbed; and these conditions will be accompanied by an unusual and long-continued flow of blood. Subinvolution, congestion and inflammation, hyperplasia, tuberculosis, cancerous and fibrous deposits in the muscular structure, and chronic and acute endometritis, in addition to preventing the normal deciduous changes in the mucous membrane of the uterus, maintain a permanent hyperæmia, and thus render the womb prone to large losses at each return of the menstrual period. We have in fact abundant reasons for assuming that chronic hyperæmia, no matter how produced, will, by virtue of the malnutrition connected with it, prevent menstrual changes from being effected in an orderly manner, and thus render the mucous membrane more frail in organization, and consequently incapable of resisting the force of vascular pressure to which it is periodically subjected.

Besides the causes of uterine hyperæmia last alluded to, and existing within the tissues of the womb, there are many other *outside pathological conditions* acting in a different way. Some of these cause venous hyperæmia by mechanical retardation of the circulation, while others give rise to both arterial and venous hyperæmia by nutritional attraction, and others again cause arterial hyperæmia alone, by forcing unusual amounts of blood into the organ. Among the most frequent and important causes of *venous* retardation are displacements and flexions of the uterus—procidentia, retroversion and retroflexion—the former by stretching the

veins and rendering their course more tortuous, the latter by twisting them and thus lessening their calibre; exudations into the cellular tissue and peritoneal pouch, from cellulitis and local peritonitis, and effusions of blood in the cul-de-sac of Douglas, in retro-uterine hematocele, by pressing upon the veins, prevent a free return of blood from the uterus, and thus cause venous hyperæmia. Retardation of movement in the uterine veins may also be caused by obstruction to the venous circulation quite remote from the womb, as by the pressure of a tumor upon the ascending vena cava, by a loaded condition of the large intestines, by dislocation or enlargement of the liver, by obstruction to the free passage of blood through the heart from valvular disease, and even by certain pulmonary affections.

In the class of causes giving rise to both *arterial and venous* hyperæmia, may be mentioned fibrous, fibrocystic, polypoid and fungous growths of the fibrous structure of the uterus. These all increase the flow of blood to and through the vessels of the uterus, both arteries and veins are increased in capacity, and to these changes is added general hypertrophy. In these cases, the hyperæmia of all the tissues is sometimes enormously great, and the losses of blood are proportionally large and dangerous; the hemorrhage, unlike that from venous obstruction, is not checked by the emptying of the vessels, but continues until the arterial and cardiac *vis-a-tergo* is weakened by approaching syncope.

Causes producing *arterial* hyperæmia alone, are hypertrophy of the heart, general plethora, febrile excitement, and violent exercise. The uterine hyperæmia in these cases is caused by unusual arterial and cardiac pressure alone. When not attended by local pathological conditions, the hemorrhage in these cases is not apt to be serious.

Other not uncommon causes of hemorrhage from the womb are various *diseases of the blood.* Among these may be mentioned scurvy, leucocythæmia, chlorosis, albuminuria and syphilis. It is not likely that the vice in the composition of the blood is the sole causative influence operating in the above-named conditions. In scurvy, for instance, we know that the solid tissues—whether as a primary condition or as an effect of the blood-changes—are diseased, the capillaries more fragile than natural, and consequently less capable of resisting the cardiac impulse. As evidence that the vicious condition of both blood and solid tissues is the cause of uterine hemorrhage in scurvy, the well-known fact may be added that bleeding is very easily provoked in other mucous membranes. It is the more likely to take place from the mucous membrane of the uterus, because of the great normal fluctuations in the circulation of that organ, and also because the vitiated state of the blood would naturally cause disturbance in other conditions attendant upon menstruation, especially the decidual changes. It will be seen therefore that the peculiarity in the operation of this variety of cause, is not due to the presence of local or general hyperæmia from retardation of the venous circulation, or from arterial and cardiac pressure, but is due to the tendency of the blood to escape through the walls of the vessels, and to the inability of the capillary tubes to resist the circulatory force ordinarily applied to them.

As another cause of hemorrhage from the womb, must be mentioned the well-known law of the human system to continue a long-established *habit*, after the original cause is removed. This is probably the only rational explanation of those rare uterine losses which are sometimes observed in pregnancy, and in cases where both ovaries have been re-

moved. The habit of bleeding continues after the ovarian, reflex, nervous influence has been withdrawn from the uterus.

Still another rare, yet very dangerous, cause of uterine hemorrhage, is that known to surgeons as the *hemorrhagic diathesis*. The writer has seen one case in which he believes that the bleeding was clearly attributable to this mysterious condition, and which proved fatal. It was that of a young girl who died with her second menstrual flow.

The wide range of causative conditions found connected with uterine hemorrhage is but an inverse exhibition of the sympathetic relations of the uterus. When diseased, it exercises an almost universal pathological influence upon other organs, and as a consequence it is susceptible of being impressed to the same degree by certain morbid conditions of all important viscera. In this assembly of intelligent practitioners it will not be regarded as making an undue claim to say, that the practice of gynæcology requires a more thorough theoretical and practical familiarity with the details of all the branches of medicine than any other of the so-called specialties. We are not prepared to treat the most common of female diseases without being able to scan with scientific scrutiny every organ and function of the body. Nor until we can compete successfully with the general practitioner, the surgeon, the alienist, and the neurologist, in the therapeutic processes of their respective departments, may we hope to exercise in the highest sense the office of the gynæcologist. These remarks apply with force to the comprehension of the causes and treatment of hemorrhages of the unimpregnated and non-puerperal uterus.

Treatment of Metrorrhagia.

I find it quite impossible to satisfy myself as to the best order in which to bring forward the various measures proposed for treating uterine hemorrhage. Those which have for their object the removal of the causing conditions, properly fall under the head of *curative* means; while those which we employ to stop the bleeding temporarily, until the remedies of the first order have accomplished their purpose, seem as naturally to belong to the category of *palliative* measures. We find in each of these divisions, however, remedies which act in both ways, and the palliative means are often radical and energetic. Notwithstanding the many obvious deficiencies in this arrangement, it seems to me to be the best that I can adopt.

Palliative Treatment.—Before entering into a detailed description of the more essential, remedial methods of curing the various forms of hemorrhage, it will be profitable to consider some of the important, minor measures which are applicable in almost all instances. As the great majority of hemorrhages occur at the menstrual periods, we often have opportunities of adopting measures in anticipation of them. These measures are sometimes calculated to entirely prevent an exaggerated flow, and at others to very much modify it; and in all to greatly promote the action of more direct remedies. The patient should abstain from all causes of local or general, vascular or nervous excitement. Among these causes are mental and bodily fatigue, emotional excitement arising from certain social relations, sensational books, and the contemplation of erotic objects. The patient should also abstain from stimulating drinks and highly seasoned food; her clothing should be loose and cool, so that no

part of the body may be constricted, and the genital organs should not be too warmly covered. Her bowels ought to be kept regular, or rather free. The secretions from the skin, liver, and kidneys should be maintained as nearly as possible in a normal condition, and tonics, such as arsenic, strychnia, and quinia, with digestible, nourishing and unstimulating diet, should be given in quantities sufficient to keep the health up to the normal standard. Other things which will contribute very greatly to good results, are plenty of pure air, night and day, and moderate, muscular exercise. Many other general directions will suggest themselves, which I cannot stop now to mention.

When the time for the paroxysm has arrived, and the hemorrhage has commenced, isolation, quietude, and recumbency are very important precautions to be enjoined. Position indeed may be made to do much good of itself. If the hemorrhage is not severe, mere recumbency will be sufficient; but if it is protracted, the hips should be elevated, and sometimes it will be beneficial to raise them so high as to cause the blood to gravitate to the fundus uteri, and to fill the whole genital canal before any of it passes out. To a considerable extent this may be made to act as a tampon. The position chosen to effect this object may be on the back, or upon the knees and chest. If the latter position can be commanded, it is much the best, as the reversal of gravitation is more complete. Cold and acid drinks, cold applications to the hypogastric and sacral regions, hips and vulva, and in the vagina, are also among the remedies applicable to almost all cases.

Many practitioners value astringents, administered internally, in uterine hemorrhage, but I have found so little benefit from them when not given with opium or belladonna, that I seldom resort to them. Where there is much pain in the pelvis, and a dry state of the skin, opium and ipecacuanha are often very servicable. Lobelia, gelsemium, digitalis, aconite, and veratrum viride, may also be mentioned as very frequently applicable where there is vascular and nervous excitement.

Perhaps the medicine most generally applicable in paroxysms of uterine hemorrhage, is ergot. In all cases of local arterial hyperæmia, as in tumors, hyperinvolution, etc., we may expect good from its employment. But it will generally fail to be useful when the uterine hyperæmia is venous, as in retroversion, pelvic infarction from periuterine effusion, abdominal tumors, etc. It will not act efficiently in cases of carcinomatous deposit, granulations of the mucous membrane, or tuberculous degeneration of the fibrous texture of the uterus.

In the more dangerous instances of hemorrhage, these moderate palliative measures are not sufficient. In some, the amount of loss is so great, and occurs so suddenly, as to threaten the life of the patient. Or, if life is not in danger, the discharge may be sufficient to lead to other very serious, remote consequences. These emergencies are to be met by such means as will promptly arrest the flow, and keep it in check until curative processes can be instituted. Fortunately this may be done with great certainty by mechanical and chemical appliances generally at our command. The genital canal, practically closed at its upper extremity, and conveniently open at its lower termination, admits of being impacted to an impermeable degree, and allows of topical applications to its whole extent. In using either form of these topical measures, the effort should be made to apply the remedy as near to the bleeding point as possible.

When practicable, we may secure the best effects by employing the mechanical and chemical means conjointly. The *mechanical* means em-

brace the different forms of the tampon. Plugging arrests the hemorrhage by forcibly opposing the evacuation of the blood, and by thus imprisoning it in the smallest cavity. The blood so confined, coagulates, and fills the space between the tampon and the bleeding surface with a fibrinous clot which also closes the mouths of the vessels. When plugging is skilfully performed, the relief is temporarily perfect, and gives us valuable time for other treatment, or allows the cyclical period to pass, when the hyperæmia subsides. The *chemical* means consist in the use of powerful hæmostatics. By their chemical action upon the solid constituents of the blood, they produce a much firmer coagulum than results from mere stasis, and, if applied to the ruptured vessels, seal them up with coagulated plastic material, while if further away the coagulum forms a chemical tampon which opposes the flow toward the vulva. Used with the mechanical tampon they may be made to fill the interstices of the material of which it is formed, and thus solidify the whole mass.

In the greater number of dangerous cases of the kind of uterine hemorrhage treated of in this paper, the mouth of the womb is sufficiently patent to permit the introduction of the plugging material saturated with a hæmostatic preparation into the cavity of the uterus. Dr. Sims's method of preparing the material and performing the operation of plugging the womb is admirable in its simplicity and efficiency. The substance used is the finest article of cotton-wool, saturated with a liquid composed of one part of the strong solution of the subsulphate of iron and two of water. After the cotton has been perfectly saturated, it is deprived of the major part of its fluid by pressure, and is then allowed to dry until ready for use. The application is made by wrapping a sufficient quantity of the dried iron-cotton around a long, small piece of whalebone, and introducing it into the cavity of the uterus, when the cotton is detached and left there. If the hemorrhage is comparatively moderate, one of these pieces may be sufficient; if severe, it will be necessary to stuff the uterine cavity full. This can be best accomplished by having the patient placed on her side, and the uterus exposed by Sims's speculum. To facilitate the removal of this ferruginous tampon, the suggestion of Dr. J. R. Chadwick, of Boston, is, I think, a valuable one, viz., to wrap strong thread loosely around the cotton as it surrounds the whalebone. I prefer this method of using the hæmostatic to its injection, because the shock from the application is much less.

If the mouth and cervical cavity of the womb are not sufficiently open to permit of the introduction of this hæmostatic preparation, we may plug the cervix with prepared sponge. The first sponge should be pushed through the cervix into the cavity, and up to the fundus uteri, so that when it expands its upper end may possibly reach and press upon the bleeding point. If large enough, the cervical cavity will be completely filled and the bleeding effectually checked. The sponge should be carbolized, and well secured, before it is introduced, by passing a strong piece of twine through it, from one end to the other. Neither the cotton nor sponge should be allowed to remain longer than twenty-four hours, and half of that time is usually long enough. After removal, the vagina may be cleansed, and the application repeated if necessary. I have sometimes been obliged to renew the sponge tampon several times in the same case, though this is not usually required.

If these means are not at hand, or if the case is not sufficiently urgent to require plugging of the uterus, we may resort to the vaginal tampon.

This may be made of cotton, of which pieces as large as pullets' eggs may be used, rolled somewhat solidly, and each secured with thread and lubricated with oil or lard. A sufficient number to perfectly fill the vagina should be prepared. The patient should be placed on her left side, with the limbs flexed, and the upper one thrown forward over the other. The operator, standing at the back of the patient, inserts into the vagina two fingers of the left hand, with which he draws the perineum well backward. This will open the canal so that the clots may be easily removed with the fingers, when, with the right hand, the cotton may be placed with great facility in the vagina. At first several on the os, and around it, and then the whole vagina may be packed solidly under the eye of the operator. If Sims's speculum be at hand, it should be used instead of the two fingers to hold back the perineum. Or we may vary this according to the process described by Dr. Thomas, in the American Journal of the Medical Sciences for July, 1876, page 147. After dilating the vagina, "pieces of cotton, soaked in water, pressed and flattened out by the fingers, each about the size of a very small biscuit, are pressed into the vaginal cul-de-sac by means of forceps till this is filled. Then other pieces are packed firmly around the cervix until only the os is visible—a smaller pad is then pressed firmly against or introduced within the cervical canal, and the whole vagina is then filled to its lowest portion." An ordinary surgeon's roller answers admirably for a plug, and may be introduced by first inserting one end, and then passing it up in short folds until enough has been placed in the vaginal cavity to fill it up compactly. In most cases where we desire to leave the patient, the tampon should be retained by a compress and "T" bandage.

When we have reason to anticipate a sudden occurrence of severe hemorrhage in our absence, we may instruct the patient or nurse how to make and apply a very safe vaginal plug. A sponge, large enough to fill the vagina closely, may be prepared by wetting it in a strong solution of alum, or in a weak solution of subsulphate of iron, passing a piece of strong twine or tape through the centre, and then wrapping it with tape in an elongated shape to its smallest dimensions. It may then be laid aside to dry. When the necessity for its use arises the tape is removed, and the sponge thus compressed may be passed without any resistance entirely into the vagina. It is soon expanded by the blood, and the vaginal cavity thoroughly filled. A few of these sponges prepared ready for instant use will enable the patient to prevent any material loss until the practitioner arrives. The plug may be removed by the tape or twine whenever desired. The plug may be allowed to remain from eighteen to twenty-four hours, when it should be withdrawn, and, the vagina having been thoroughly cleansed with carbolized water, replaced if necessary.

Curative Treatment.—The central nervous disorders which cause uterine hemorrhage will, when recognized, require the treatment set forth in the various works upon these subjects. I need not, therefore, dwell here upon the management of the spinal and cerebral inflammations and irritations, nor upon the numerous forms of emotional excitement which lead to metrorrhagia. The treatment of the reflex, morbid, nervous influences, belongs more particularly to gynæcology, and will call for all the ingenuity and varied knowledge taught in that branch of practical medicine. The ovarian derangements, being the more obvious and common of these, may be noticed first. Our means for replacing and retaining in position displaced ovaries are very meagre. The patient must be

confined to the horizontal position, with the pelvis elevated as much as practicable. The knee-chest position is the best, and may often be maintained for a considerable part of the twenty-four hours. Generally the displacement is accompanied by congestion or inflammation of the ovary, which increases its size and weight. When this is the case, the treatment, in addition to position and quietude, recommended during the intermenstrual period, will consist in the use of counter-irritants, hip-baths, hot water vaginal injections, and alteratives, administered internally, or applied externally in the form of ointments, or per vaginam as suppositories, injections, etc. Among the alteratives, the muriate of ammonia will be found very valuable. When there is much debility, the bichloride of mercury, dissolved in the compound tincture of cinchona, is among the very best. Iodine, iodide of potassium, and iodide of iron should also be named as efficient alteratives in these conditions of the ovaries. One derivative measure which I desire to mention as especially beneficial in these cases is dry cupping over the sacrum, often repeated. To be effectual the cups should be large, and allowed to remain for a long time, say an hour or more. When there is much pain in the ovarian regions, suppositories of the extract of belladonna and ergot, once or twice daily, will not only relieve the pain, but will do much towards allaying the inflammation.

When hemorrhage occurs in a nursing woman, if it is of sufficient gravity, the child should be weaned. At the time of the paroxysm, if the breasts are tumid and tender, cold may be applied to them to relieve both the uterine hemorrhage and the mammary congestion. These patients require invigorating measures in connection with the local treatment of the breasts.

The vesical or rectal tenesmus which gives rise to hemorrhage must be treated by the remedies found necessary after investigating the cause. So, also, with diseases of the stomach, bowels, and liver, as well as with the effect of cold or of long-continued heat.

Subinvolution and chronic congestion of the whole uterus require to be treated very much alike, by the application of such remedies as condense the uterine tissues—ergot, belladonna, quinia, electricity, cold injections, compresses and sitz-baths. When there is no tenderness, ergot will be found a very efficient remedy, if administered for a sufficient length of time—several months for instance. If there is considerable tenderness and pain, belladonna and quinia will be best adapted to the case. Ergot in some instances induces sensitiveness and heat in the pelvic organs, and then it should be used very cautiously. This effect of ergot is especially noticeable when there is chronic local peritonitis or cellulitis. If there is a high degree of sensitiveness, a mercurial alterative may very properly be given in connection with the belladonna and quinia, and a good form for administering it is the bichloride of mercury dissolved in the compound tincture of cinchona; or we may use mercurial inunction, or mercury in suppositories. I have not been able to do much good in these cases with iodine in any form. If given with iron, as the iodide of iron, it has occasionally a good tonic and alterative influence. These conditions of the uterus are very obstinate, and require a continuous treatment, oftentimes for many months.

The treatment of endo-metritis is too well described by systematic writers on gynæcology to require more than a very brief notice. It consists mainly in a persevering continuance of stimulating applications to the diseased mucous membrane. I do not like the term caustic, for

even the strongest remedies used for this purpose are applied so sparingly that their effects are little more than strongly stimulative. In the light of our present knowledge of the processes of menstruation, these remedies, as suggested by Dr. Atthill, should be resorted to immediately after the monthly flow has ceased. By common consent of the profession, in this country, the treatment of granulations of the uterine mucous membrane consists in scraping them off, and the teaching of Sims and others has made the process sufficiently familiar not to require description here. Although not curative, the same treatment may be mentioned as most efficacious in arresting the hemorrhages resulting from cancerous granulations. In a discussion of Dr. Hanks's recent paper, Dr. Peaslee gives the very judicious advice not to cut into the sound tissue in the process. In cases of malignant fungus, we may often arrest the tendency to hemorrhage by injecting alcohol, by means of a hypodermic syringe, deeply into the substance of the part. This process frequently repeated sometimes retards the growth very materially. The tincture of the chloride of iron, similarly used, will often have the same effect.

The various conditions which give rise to retardation of the venous circulation, require to be treated according to the improved methods now so well understood by the profession. The displacements of the uterus which are arranged among these conditions, must be corrected by the various ingenious appliances designed for this purpose. And this may be done during the time of the preternatural flow with the expectation of moderating it at once.

Dr. T. D. Fitch, of Chicago, has recently proven this last assertion in the management of a case occurring in a patient who had just passed the menopause. The uterus was retroverted, and all the means resorted to did not even moderate the metrorrhagia until the organ was elevated and retained in position by an appropriate pessary, when in a short time the bleeding ceased. After the subsidence of the flow, the patient removed the instrument, on account of some slight inconvenience which it gave her, but the flooding began again in a very few hours, and continued, notwithstanding repeated efforts to arrest it, until the pessary was once more introduced, when the hemorrhage again subsided, and has not returned. The patient was still wearing the pessary when I heard of her case.

The subject of the treatment, and especially the surgical treatment, of tumors of the uterus which cause arterial hyperæmia and uterine hemorrhage, is too extensive to be entered into in this paper; and I refrain from considering it the more willingly because it will no doubt be exhaustively and ably discussed by Dr. W. L. Atlee in the paper which he is to read before the Section. I cannot, however, forego the duty of making some suggestions as to the method of treating these growths with internal remedies.

The extreme danger from hemorrhage, connected with fibrous tumors of the uterus, is not so often encountered since the profession has become acquainted with the great influence exerted upon certain conditions of the unimpregnated uterus by ergot. It is now understood that fully seventy-five per cent. of hemorrhagic cases of fibrous tumour of the uterus may be rendered free from danger, as far as the hemorrhage is concerned, by an intelligent and persevering use of ergot, and that in twenty per cent., the tumors may be removed. In using ergot, in these cases, the mode of administering it cannot be uniform. Some patients cannot take it in any sufficient doses to answer the purpose; some cannot take

it in the form of fluid extract, or wine, but can take the solid extract in the form of pills; others can take it in any form. When the stomach will not tolerate the ergot, it may be given hypodermically, or per rectum in suppositories, and I believe that it can be made to act efficiently when given in any of these ways.

Whatever method or form we may adopt in the administration of ergot, we should give it in sufficient quantities to produce a sensible effect by causing contractions and pain, and there is no better rule to guide us, as far as I can judge, than to give it in increasing doses until that result follows. Twenty minims of the fluid extract, three times a day, will sometimes be sufficient, while some patients, on the other hand, will require twice or three times as much to produce the effect.

The length of time required to obtain the ultimate effects of the ergot in these doses, varies as much as the quantity required. The tumor will sometimes diminish very rapidly, but generally the decrease in size is quite slow. From one month to over a year may be required to accomplish a cure when it can be accomplished at all. Ergot is sometimes very violent in its action, but by withdrawing it temporarily, lessening the dose, or combining and alternating it with anodynes, it may be safely managed. Although I have given it extensively, and for a long time together, I have not seen anything worse than inconvenience arising from its use.

It will not, of course, be expected that I should enter into a consideration of the treatment of scurvy, leucocythæmia, albuminuria, or syphilis, as general conditions causing uterine hemorrhage, both for want of time and because they are subjects well treated of in works on the general practice of medicine. Our ignorance of the last of the causes mentioned in the first part of this paper, viz., the hemorrhagic diathesis, will also excuse me from dwelling upon the treatment of that mysterious condition which afflicts some unfortunate individuals belonging to our race.

Discussion on Dr. Byford's Paper.

After the reading of the preceding paper, Dr. William Goodell, of Philadelphia, said:—I did not wish to begin the discussion, but as others are backward I will try to start the ball. I was not able to hear all that Dr. Byford said, but some of the points made by him are of extreme interest. I wish to refer to the almost absolute inertness of astringents when given by the mouth in cases of uterine hemorrhage. The text-books laud them, but I have found most of them useless. In my opinion, the canonical pill of acetate of lead and opium would be inert, save for the opium in it, the latter being a valuable hæmostatic. A pure astringent which I have found of much value is gallic acid—not administered in the ordinary dose of five grains, but in doses of from twenty to thirty grains every two hours, or more according to the urgency of the case. I have discovered no bad effects resulting from its use, although I have given half an ounce in the course of a day. It is a bulky and disagreeable remedy, but I mix it with some table-syrup or with molasses, and have found it the only astringent of any efficacy in stopping these hemorrhages. Ergot acts well, especially when used hypodermically, but I know of cases where it has increased the hemorrhage; I do not now refer to cases of fibroid tumor in which it will sometimes so act, but to other cases of metrorrhagia in which I have found it to increase the discharge from the uterus in a way that is inexplicable to me. Free dilatation of the cervix by tents will alone often cure hemorrhage. The causes of uterine hemorrhage are sometimes obscure, and I

have sometimes been humiliated by not discovering them. I have dilated the cervical canal, passed my finger into the uterine cavity, made careful examination, and yet have found no tangible cause. There are other causes beside granular conditions of the lining membrane, which may be so minute as to elude an examination by the finger. When I could find no explainable cause for such hemorrhages, I have treated them empirically, by introducing into the cavity pure nitric acid. I refer particularly to the case of an unmarried lady, in which the hemorrhage lasted for weeks at a time. I fully expected to find a polypus, but did not. The flow was arrested by nitric acid, but it shortly began again; I then used intra-uterine injections of iodine, but the benefit was only temporary. At my request Dr. A. H. Smith also examined the patient, but failed to discover any cause. The hemorrhage finally yielded to ergot, which in the first instance had failed. To this day I am ignorant of the cause of this hemorrhage. I have found the tincture of iodine of use, though it is not infallible. In using it, I first stretch open the os with a dilator, and then inject about a fluidrachm. It has the great advantage of not forming hard clots. There is a plain, homely remedy, which I have successfully used in menorrhagia when others have failed—cinnamon tea, or cinnamon boiled in milk. Heat applied to the spine has also proved of benefit, though not invariably. I am pleased to find that the bichloride of mercury has been referred to by Dr. Byford in high terms. This is a favorite remedy of mine, not only as an alterative, but for its property of increasing the number of red blood-corpuscles. When given for two or three weeks, but not longer, in cases where much flooding has taken place, it renews the blood rapidly, fattens up the patient, and is in my opinion a fine tonic, especially when combined with iron and arsenic.

Dr. J. W. Rosebrugh, of Hamilton, Canada, said:—I think that Dr. Goodell has failed with the acetate of lead because his doses have been much too small. Dr. Workman, of Canada, has given half a drachm at a dose, and claims that with large doses he can stop any hemorrhage at once. I do not, myself, like the remedy, but in cases of extremity it may be effectual.

Dr. Edward M. Hodder, of Toronto, said:—The subject is limited to cases of non-puerperal uterine hemorrhage only. But such doses of acetate of lead as are referred to by Dr. Rosebrugh are only to be used in cases of post-partum hemorrhage. I have employed the tincture of cinnamon largely, and have also used the tincture of cimicifuga, as well as sulphuric acid, but always in conjunction with local treatment. I have injected the perchloride of iron into the uterus until the acid has passed through the Fallopian tubes into the peritoneal cavity, but with only temporary inconvenience. I have also used the persulphate of iron in relaxed and flabby conditions of the uterus. I think that if astringents were used, and the uterus were kept in place, cases of hemorrhage would be more amenable to treatment than is generally supposed.

Dr. Alexander R. Simpson, of Edinburgh, said:—The subject is an important and practical one. It appears, from what I have heard, that uterine cases are much the same on both sides of the Atlantic, and that no one treatment will suit all cases. I have a general impression as to the inutility of astringents, and yet there are cases in which I would use any of them. While agreeing with Dr. Goodell as to the efficiency of gallic acid (which I prefer above all others), and in some cases of sulphuric acid, I wish to mention another agent which often acts admirably as an astringent, and that is the oxide of zinc. I know of cases which have been carried over by one or two-grain doses thrice daily. It is a truth, however, that physicians are often left in the lurch, and have to resort to direct local treatment. The first direct application should be in the shape of vaginal plugging, although I have but little faith in the value of the tampon *per se*. For instance, in some cases the hemorrhagic habit is kept up by the terror and dread of the patient, but the use of the plug by stopping the flow gives her confidence, and there is a corresponding lessening of the menorrhagia. It is difficult at times to apply the tampon so as to make it effective, and I therefore think that plugging the cervical canal i

the better plan, especially as it opens the way for subsequent exploration and treatment. As to direct applications to the uterus, nitric acid is good in some cases, but where a hemorrhage is in progress, I do not find it so effective as the perchloride of iron. In cases of enlargement and of thickening of the mucous lining, it would be important to scrape off the redundant portions by the curette, as recommended by Récamier and Sir J. Y. Simpson. In one case, I simply scraped off the thickened membrane, and, contraction of the womb being kept up by ergot, the patient recovered. The blood at times also gets into such a watery condition as to tend to the continuance of hemorrhage, and then special constitutional treatment is required.

Dr. Thomas W. Gordon, of Georgetown, Ohio, said:—I think very highly of the value of quinia in cases of non-puerperal hemorrhage occurring in malarious districts, or in broken-down constitutions, and think that in such cases it should never be omitted.

Dr. J. A. Campbell, of Grafton, West Virginia, said:—I believe with Dr. Gordon in such a thing as an intermittent uterine hemorrhage, and know that in malarious sections of the country we could not treat hemorrhage without quinia. In most cases, however, the hemorrhage is dependent upon congestion of a displaced womb. The circulation of the blood being prevented by prolapsus, congestion arises, engorgement follows, and then there is a hemorrhage at every recurrence of the menstrual period. I have in my practice insisted upon nightly replacement of the organ by the patient herself, for no physician could attend to this, unless he had but the one case; I consider replacement the chief prophylactic for engorgement and the consequent hemorrhage. This replacement can be effected by the woman herself, by first assuming the knee-breast position, and then by either separating the labia with two fingers, or by introducing a short glass tube into the vagina. I have used iced water also with advantage, but of course not during the menstrual period. Or a gallon of water may be injected every four or five hours, not letting the temperature be much below 60°. In the water I sometimes dissolve sixty grains of the sulphate of iron. The fluid extract of ergot I often give hypodermically, or internally in doses of thirty or forty drops. Dilute sulphuric acid is a favorite remedy with me; I have known women, who from continued hemorrhage have become debilitated, and whose menstrual flow has been so lengthened in duration that the interval between each period has been reduced to a very few days. In these patients, by examination with the speculum, I have found polypoid granulations; but a few applications of nitrate of silver have changed the entire aspect of the case.

Dr. Thomas F. Rochester, of Buffalo, said:—Quinia should be used in all cases of chronic hemorrhage, whether under malarious influences or not, but I am not in favor of full doses; quinia acts upon the capillaries, and thus exerts a good effect. I do not therefore think that its use should be confined to cases of malarious hemorrhage alone.

Dr. Edward H. Trenholme, of Montreal, said:—There are two modes of treatment, the local and the constitutional. The former is adapted to check the actual flow when the patient is in imminent danger. I employ "Sims's" iron cotton, prepared in proper-sized plugs. As a constitutional remedy, where it was difficult to find the cause, I have found oxide of silver, in combination with opium, very efficient.

Dr. B. F. Sherman, of Ogdensburgh, N. Y., said:—I can also recommend the styptic cotton for use as a tampon, and, in granulations, a saturated solution of permanganate of potassium. In obscure cases I give internally one grain of the oxide of silver thrice daily, combined with one-quarter of a grain of opium.

Dr. Charles Shepard, of Grand Rapids, Michigan, said:—While I am a warm advocate of the use of quinia, I desire to laud a mode of local treatment which I employ. I use an elastic rubber bag into which I inject iced water.

This is carried up through the cervix, and it applies itself so closely to the bleeding surface as to be very efficient in stopping the hemorrhage.

Dr. H. D. VOSBURGH, of Lyons, N. Y., said:—Gallic acid is, I think, the only astringent from which much benefit can be derived in uterine hemorrhage. All physicians have pet remedies, and pet plans of applying them. I have found the ordinary solution of persulphate of iron effective; I inject it into the uterine cavity by means of a glass tube with a rubber bag at one end, and cannot recall a case of non-puerperal hemorrhage which has not yielded to this remedy.

Dr. ROBERT BURNS, of Philadelphia, said:—In an experience of forty years, I have seen many cases of this character. In my early practice, when the speculum was hardly known, my dependence was upon large doses of astringents, which often disappointed me. But since the discovery of the speculum I have much less trouble. My system is a simple one, and varies but little. I first attend to the state of the constitution—if the patient is weak, giving her tincture of chloride of iron, quinia, and aromatic sulphuric acid. I then use a combination of a drachm each of tannic acid and sulphate of zinc, in an ounce of glycerine, which I apply to the interior of the uterus, through the previously dilated cervical canal, using cotton saturated with the mixture. I repeat this several times, and brush the cervix with the same, putting the patient on gentle purgative treatment. There are cases of extreme hemorrhage where ordinary methods fail, but most of them are amenable to this mode of treatment.

Dr. THEOPHILUS PARVIN, of Indianapolis, said:—We must all agree, from the discussion and from the number of remedies that have been suggested, that the uterus is an organ which can be abused with impunity. It has been said that we must find the cause of the hemorrhage: true, but in the mean time one's patient may bleed to death. Stop the hemorrhage first, and find out the cause afterwards. There is one method which has not been referred to, and that is vaginal injections of hot water. This is a first-class remedy. Hot-water rubber bags, applied to the back, have also been found efficacious. The difficulty of local treatment is often due to the fact that the physician shrinks from the examination of an unmarried woman; but desperate cases require modesty and shame to be put aside. The remedies spoken of may be empirical, but they are the best in such cases. As to local treatment, there is often some disorder with the parts. Some practitioners use the curette, while others say that it is murder to do so. Mucous polypi in the cervical canal are irritants, but are not the source of the hemorrhage. They cause an increased flow of blood to the parts that are irritated by their presence, and there is a solution of continuity as the result. Remove these polypi, and then apply tincture of iron. I thought that I had made a discovery when I used a small forceps instead of the curette for the purpose of pinching off small granulations, but I have found that others had used them before me. The hemorrhage is not an entity in itself, but merely the expression of something else. We cannot cure the patient without finding out the cause, which, in doubtful cases, I believe is often an inflammation of the lining membrane of the uterus.

Dr. S. S. TODD, of Kansas City, Mo., said:—I wish to remove the subsulphate of iron from the list of injurious remedies. I used it shortly after its introduction by Dr. Barnes, and have reported eight cases, in all of which it was successful, though the hemorrhages were all dangerous. I believe that many lives have been saved by its use. I desire to reiterate that the subsulphate of iron is absolutely innocuous.

The President, Dr. ROBERT BARNES, of London, said:—I have been much impressed with the great advantage of these meetings; the members of the Section have heard a variety of expressions from all parts of this great continent, and every expression of individual opinion has embodied much that is valuable. I have received several new ideas while the discussion on this interesting question has been going on. In London, we know but little of

malarial hemorrhages; but we have found quinia a valuable means of controlling bleeding, as it contracts the uterus, and is otherwise of service to the system. I always use it in cases of hemorrhage from subinvolution, and do not think a merely local treatment all that is needful in such a condition. I have noticed the law of habit mentioned by Dr. Simpson, for hemorrhages will sometimes take place when the uterus is apparently healthy, not only independently of ovulation, but often after the climacteric period. These hemorrhages are largely attributable to regional attraction of blood to the uterus, for that organ is liable to regional hemorrhage, even when there is no disease of a local character. The treatment must be local or general, and sometimes it is necessary to resort to both. Topically, the best plan is to dilate the cervix and inject the perchloride of iron. Astringents by the mouth are of use at times, and, of these, I think with Dr. Goodell that gallic acid is the best. The heart-action often has an effect on the hemorrhage, and by using aconite and other remedies to reduce cardiac action, there will be a corresponding reduction in the flow of blood. In some cases in which the cause of hemorrhage could not be ascertained, I have used, with excellent results, the witch-hazel, which I believe to be a native of this country. Although the curette has undoubtedly been of service in many cases, yet I condemn its use, for it is often followed by furious bleeding, and the growth of small malignant excrescences is more rapid after using it. Besides, it is, at best, a dangerous instrument, and requires to be handled with the greatest care. In one year I lost two patients from its use.

Dr. Byford, in reply, said:—Quinia is only second to ergot in causing uterine contractions, and is an admirable remedy. I have known of miasmatic conditions producing hemorrhage in non-puerperal cases. Quinia is of use in these cases, especially in causing condensation of the uterus. In the vast majority of cases, hemorrhage from a non-puerperal womb is owing to one of two conditions, either hyperæmia or a vitiated state of the uterine mucous lining, from inflammation or from growths. For the former condition I use ergot and local remedies, such as the tincture of iodine, but not as intra-uterine injections. In my experience, uterine hyperæmia and hypertrophy need the application of a strong astringent to the neck of the womb alone, for the body of the uterus can be made to contract by applications to the external and internal surfaces of the cervix. Local remedies can be applied in many different ways. The other common cause of hemorrhage is a disorganization of the lining membrane of the uterus. Hemorrhage becomes more easy when this mucous coat is not firm, because it gives way more readily. Topical treatment is here indispensable. When bleeding has occurred after the menopause from a determination of blood to the womb, I have been able to do more with large doses of quinia and iron than with ergot or with anything else. I do not consider ergot particularly valuable in such cases. The vaginal plug is of great use when used properly and thoroughly. It should not simply be pressed against the os, but firmly packed in front and behind the cervix, in order to compress it. I have, in my own practice, been rather timid in regard to injecting fluids into the womb, probably too much so, but I avoid such treatment wherever it is possible to do so.

THE MECHANISM OF NATURAL AND OF ARTIFICIAL LABOR IN NARROW PELVES.

BY

WILLIAM GOODELL, A.M., M.D.,

CLINICAL PROFESSOR OF THE DISEASES OF WOMEN AND OF CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA.

"Opinionum commenta delet dies, naturæ judicia confirmat."

CICERO, *De Naturâ Deorum.*

In studying the mechanism of natural and of artificial labor in narrow pelves, let us first inquire what is meant by a narrow pelvis, and what are its kinds.

A pelvis with a true conjugate (*conjugata vera*) measuring less than four inches constitutes a narrow pelvis. For, although the biparietal diameter of the average fœtal head at term measures less than four inches, the working space between the promontory of the sacrum and the symphysis of the pubis is lessened by double the thickness of the uterine wall, and by double that of the vesical wall. While, therefore, the actual conjugate is ample for an average head to pass, the virtual conjugate may be too small. Thus, according to our best authorities, a standard head in a pelvis measuring in its conjugate 3.75 inches—viz., half an inch less than that of the average-sized pelvis—constitutes a difficult labor.

A spontaneous delivery is not impossible under such circumstances, but the forceps will usually be needed; sometimes, indeed, craniotomy. Every line below this measurement greatly increases the difficulties of parturition. For instance, out of thirteen vertex presentations in pelves measuring at the least 3.75 inches, Dubois had three cases of craniotomy or of cephalotripsy. In conjugate diameters between 3.75 and 3.1 inches, he had ten presentations at term of the vertex, and one of the face. Of these, two ended spontaneously, two were delivered by the forceps with the death of one child, and seven needed the cephalotribe.[1] Baudelocque contends that out of five hundred children at term and of average size, hardly one will be delivered alive through a pelvis of three inches. To this, Dezeimeris[2] adds that one of 3.25 inches does not give much better results, and that one of 3.5 inches also offers to the child a very dangerous passage. Joseph Clarke gives,[3] as the result of an experience of 14,077 cases of labor, that "three and a half inches is the least diameter" through

[1] Management of Labor in Contracted Pelves. By Wm. H. Jones. This author, it is true, makes these cases occur respectively in pelves whose conjugates measured "over 3.5," and "between 3.5 and 3 inches." But since he has adopted the classification of Dubois, these figures seem to me incorrect. For Dubois's first and second categories of deformed pelves are those in which the conjugates measure respectively, at the least, 3 75 inches (au moins 9.5 centimètres), and between 3.75 and 3.1 inches (au plus 9.5 centimètres et 8 centimètres au moins). This information I get second-hand from Cazeaux, and not from Dubois, whose thesis is beyond my reach.

[2] Dictionnaire en 30; Art. Accouchements Prématurées, p. 427.

[3] Contributions to Midwifery; by T. E. Beatty, p. 23.

which he has known "a full-grown fœtus to pass entire." Chailly-Honoré says,[1] "The forceps will frequently extract a living child through a conjugate of over nine centimetres (3.54 inches), sometimes, indeed—although this is very rare—under this size." From these facts, the broad rule may be laid down that, when the short diameter of the brim does not exceed the biparietal diameter of the child's head, the unaided efforts of the mother will in general be inadequate to effect a safe delivery, and that even with instrumental aid the life of the child will be greatly imperilled.

The most common kinds of narrow pelvis are three in number:—

(1) The simple, flat pelvis, or conjugate narrowing with correlative transverse widening.

(2) The generally and uniformly narrowed pelvis, in which all the pelvic diameters are symmetrically shortened.

(3) The generally narrowed, flat pelvis, which combines the bone-lesions of the other two, but in varying proportions.

Of these three varieties, the one most commonly met with is the simple, flat pelvis, in which the lesion is limited mainly to the brim and to its posterior half. Practically the obstruction is a marginal one, and is confined to the sacral pole of the conjugate diameter. In the second variety—or the generally and uniformly narrowed pelvis—the obstruction is not a marginal one, nor of limited area, but diffused over every plane of the pelvic canal. In the third variety, the obstruction depends upon the preponderance of conjugate or of transverse narrowing, and is, therefore, either mainly at the brim and marginal, or mainly in the pelvic canal and diffused.

Since "Art is the imitation of Nature, and those will best succeed in any science who closest watch her operations,"[2] let us next note the mechanism of an unaided head-first labor in these different kinds of narrow pelvis.

In the generally and uniformly narrowed pelvis, the mechanism is very analogous to that which takes place in the standard pelvis, but is of course attended with more delay. The head enters the brim synclitically and with the normal Solayrés obliquity—that is to say it engages in one of the oblique diameters of the brim, but without lateral (Nægele's) obliquity. It will also be strongly flexed (Rœderer's obliquity), because the resistance at the brim is equal on all sides, and the shorter hind-arm of the head-lever must therefore descend. The head also begins to flex at a higher plane of the pelvic cavity than in the standard pelvis. For flexion in the latter is chiefly brought about by the resistance of the os uteri; in the former by the more highly situated brim. During the descent of the head, the synclitic movement is preserved except in so far as vertical or lateral shearing interferes with it. Since the absolute conjugate narrowing is rarely great, and the general narrowing is symmetrical in all directions, the furrows or the fractures of the cranium are by no means so common as in the other varieties of deformed pelvis. But, when present, they usually start from the boss of the parietal bone and run more or less parallel to the sagittal suture, as in cases of fracture reported by Lizé[3] and D'Outrepont,[4] and one of depression of the skull by Danyau.[5] It must, however, be borne in mind that, while the bone-furrow always

[1] Accouchements; Paris, 1867, p. 649.
[2] The Present State of Midwifery in Paris; by A. Tolver, 1770, p. 22.

[5] Ibid., p. 49.

indicates the transit-line, the fractures do not, as they may radiate from it in every direction.

When left to the unaided efforts of nature, the typical mechanism of a head-first labor in the flat pelvis, or in one whose brim is narrowed mainly in its conjugate diameter, is as follows:—The hind-head offers its biparietal diameter at the conjugate, but cannot enter. The resistance being nearer to the occipital end of the head causes extension, and the fore-head dips. As the fore-head descends, the sagittal suture, losing its Solayrés and Rœderer obliquities, becomes transverse in two senses—viz., it lies in the transverse diameter of the brim, and with the two fontanelles on the same plane. The shorter and more compressible bitemporal diameter—that is to say, the upper or vault portion of each temporal region near the coronal suture—reaches the conjugate, and is driven into it, by the changed direction of the propelling force, which, acting through the vertebral column, is now thrown out of its perpendicularity to the base of the skull, and so bears at an angle directed to the forehead. Thus the head is nipped, bent in on its sacral side, and moulded to the promontory. Sometimes it is the bicoronal (the bifronto-temporal) diameter which is nipped. Hence the frequency of face-presentations in narrow pelves—a frequency, according to Michaelis, eight times greater than in normal pelves.[1] Hence, also, the ease with which the anterior fontanelle is reached, and the corresponding difficulty with which the finger touches the posterior fontanelle.

The resistance is now at a point nearer to the fore-head than to the hind-head, and the latter, therefore, begins to descend, but with the biparietal diameter *to one side* of the conjugate diameter. But the resistance of the iliac margin of the brim to the descent of the hind-head causes that portion of the cranium to expand and to mould itself to the corresponding sacro-iliac space. It also tends to shove the whole head over to the forehead side of the pelvis. In a generally narrowed, flat pelvis with absolute transverse shortening, this displacement in the direction of the occipito-frontal diameter may go on until stopped by the impact of the forehead on the opposite ilium. The head, therefore, passes the conjugate, not vertically in the bicoronal or the bitemporal diameter which first engaged, but along a transit-furrow running somewhat obliquely from that portion of the vault near the coronal suture to the base posteriorly, that is to say, in the resultant of three forces—flexion, uterine propulsion, and occipito-frontal displacement in the transverse (bisiliac) diameter of the brim. In proportion as the head descends, it becomes more and more flexed, and the biparietal diameter, which passed the brim to one side of the conjugate, will, at a later stage of labor, be found almost directly under the promontory. It must, however, be remembered that, since all the transverse diameters of the pelvic cavity are also lengthened out, the head usually descends to the floor of the pelvis with less flexion than in the normal pelvis, and anterior rotation of the vertex is proportionally delayed.

Thus, from the mechanism of natural labor in this kind of pelvis, it will be seen that the head enters the brim in a state of partial extension, or at least in a state midway between flexion and extension, and passes the short pelvic diameter by a short and most compressible cranial diameter. Further, the head usually passes the brim with also a lateral obliquity. Before the engagement of the head, the sagittal suture in a

[1] Clinical Lectures by German Authors, New Sydenham Society, 1876, p. 302.

typical case will be found very close to the promontory. To engage, the head must cant over the edge of the promontory; and during the first stage of descent this suture approaches the pubis. Later on, it begins to return towards the sacrum. This last movement is owing partly to the moulding of the posterior side of the head, and partly to the greater resistance to descent at the sacro-vertebral angle, while the pubic margin of the brim offers a smooth and glib surface. The head, therefore, pivots on the promontory as a centre of motion, and, as it were, rolls over into the pelvic cavity. It "doubles the promontory," as our honored President, Dr. Barnes, so happily expresses it.

After such an unaided delivery, or after an artificial delivery in which the application of the forceps is delayed until the head has been driven past the brim, the cranium exhibits two very characteristic shears. In the one, there is a bending in of the sacral side of the head, and a bulging out of the pubic side—it is kidney-shaped. In the other, an equitation of one parietal bone over its fellow—usually the anterior over the posterior. The site of the pressure-furrow, or of the bone-lesion, varies with the size and the position of the head, and with the shape of the pelvis. It is not found at one of the poles of the biparietal diameter, and more or less parallel to the sagittal suture, as in the uniformly narrowed pelvis in which the vertex dips *ab initio*, but at the forepart of one parietal bone, close to and more or less parallel to the coronal suture. Often it lies directly over this suture, overlapping both frontal and parietal bones, and sometimes on the frontal bone alone.

When the disproportion between the size of the head and that of the brim is relatively great, or when the conjugate is short and the head unduly ossified or bullet-shaped, engagement is often delayed. Under such conditions the head does not at once become fixed by the preliminary dip of the anterior fontanelle, but it coys at the brink of the brim without entering. Perched on the sacral shelf, it swings backward and forward, and see-saws with every fœtal movement. The finger will find the sagittal suture usually close to the sacrum, and the posterior fontanelle now in front and now behind the transverse diameter of the brim; now dipping into the inlet, anon tilting up out of it. It is momentarily fixed by each uterine contraction, and then is the time to take the position. This cranial play usually ends before long, and that by the adjustment and moulding of the bicoronal region to the conjugate, and by its consequent engagement and descent. And this may be hastened, as the late Edward Martin has shown,[1] by turning the woman over on to the side towards which the forehead looks. The breech of the child then sags over to the same side, the hind-head is lifted out of the brim by the leverage of the spinal column, and the fore-head sinks in more deeply. Whenever this dipping of the fore-head does not happen, delivery without artificial aid will be indefinitely delayed.

In the foregoing description I do not pretend to have labelled all the natural processes involved, nor to have codified every law which governs the cranial movements in narrow pelves. Nor do I contend that the anterior fontanelle always dips, for the head may be a small one, or the cranium a yielding one, or other disturbing elements may intervene. But from a study of the writings of Schrœder, Spiegelberg, Martin, and Otto de Haselberg, and also from patient bedside observation, I believe that the above mechanism is in the main correct—it certainly best ex-

[1] Prager Vierteljahrsschrift, 1868, Band ii., Analect, S. 76.

plains the behavior of the head. Since, however, the truth is not always truthlike, and since the flexion of the head with the dip of the hind-head has hitherto been taught as the mode of engagement, a few more words on this point are needful.

If, in a pelvis narrowed mainly in its conjugate diameter, the hind-head always dips, and the vertex first enters the brim, as contended by Hodge and by many others, what explanation can be offered for the indisputable fact that the anterior fontanelle, at the outset of labor, is so commonly on the same plane with the posterior fontanelle, or even on a lower plane? How interpret the well-known frequency of face presentations in narrow pelves? Again, if it can be shown, that, after such unaided labors the pressure-marks or other coarse cranial lesions are found, not at one of the poles of the biparietal diameter, which is alleged to be the implicated diameter, but, as I have asserted, at the fore part of the head somewhere near the coronal suture, then the burden of reconciling this fact to theory must rest on those who hold to the initial dip of the posterior fontanelle.

Let me summon to the stand impartial witnesses, such as had no pet theories to which their facts were trimmed. And, in these forceps days, I own to some difficulty in finding cases of labor in narrow pelves which were either neglected, as we should now call it, or left entirely to the unaided efforts of nature. Nor are the following examples noting the pressure-mark, selected ones; but the *only* ones which I have been able to collect within a short and busy time.

In describing a natural labor in a pelvis whose conjugate measured about three inches and a quarter, Mlle. Anna Puéjac, midwife in chief of the Maternité at Montpellier, says[1] that "At the *anterior* angle of the left parietal bone, there was a very considerable depression, sufficient to admit the half of an ordinary egg. It was the exact cast of the promontory." Smellie writes[2] that in a case of narrow pelvis he waited until the head was "squeezed down to the lower part of the pelvis"—that is, had passed the brim. The pains failing, he then applied the forceps along the sides of the pelvis, and caught the head, which was still *transverse*, over the face and occiput. "The child's head was squeezed into a longitudinal form, flattened on the sides, with a deep impression on the cranium *above the ear*." Again he tells us that, after a woman, who was "very much distorted," "had been in strong labor for four-and-twenty hours," he found "the head down to the lower part of the pelvis," viz., past the brim, and applied the forceps first over the face and the occiput, and then, when the perinæum began to bulge, over the sides of the head. "The head was of a lengthened form, and contorted to one side, and there was a deep impression *above the ear*."

Lachapelle contends, as the result of close observation, that "the head of the fœtus, driven through a narrow and solid pelvis, is fractured and indented near one of the frontal bones. This accident is not uncommon, and we shall cite many examples of it."[3] Again, she writes, "I have remarked with Smellie (tome ii. p. 533) that, in cases of natural labors in pelves *considerably* distorted, the depression is no longer found on the frontal region (*sur le front*), but near the temporal region."[4] Out of a number of cases reported by her I select the following: Case I. Occiput

[1] Gazette Obstétricale, Juin 20, 1876, p. 179.
[2] Collection of Cases, 1778, Collection xxvii., No. 2, Cases iii. and iv.
[3] Eleventh Memoir, p. 423. [4] Ibid., p. 429.

to the left; the anterior fontanelle *was easier to reach than usual.* A dead child was born naturally; it had the frontal boss indented and broken.[1] In another case,[2] the occiput was to the right; conjugate 3.25 English inches; a dead child was born naturally after a long labor. "The *right frontal bone*, although without fracture, offered a very marked depression which was undoubtedly due to the jutting promontory." In a third case the conjugate measured 3.25 English inches; position of the child's head not known; after six and twenty hours of labor the forceps was applied along the sides of the pelvis; "extraction prompt and easy." The left *frontal and parietal* bones were found fractured.[3] A fourth case[4] was a primipara, with a conjugate of about 3.5 English inches, and with a second position of the vertex. The forceps was applied to the sides of the head, but failed to extract; the blades were, therefore, withdrawn and applied in each ilium. There was now no further delay in delivery. The child weighed five pounds, and died twelve hours after birth. "The right *frontal* was depressed and fractured by the sacral promontory." In a fifth case,[5] the conjugate measured 3.25 English inches. The occiput looked to the left ilium; the sagittal suture lay transversely and on the sacro-vertebral angle, with the right parietal affronting the inlet.

Siebold describes a typical case of unaided labor in a pelvis of 3.5 inches.[6] At the first labor, a dead child was delivered by the forceps. At the second labor, the head presented transversely, with the occiput to the right ilium. By means of ergot a dead child was expelled. It had lesions and furrows at both temporal regions. At the third labor, the head presented transversely "with the small fontanelle to the left and the large to the right." "It was also *greatly extended* to the right," viz., the forehead dipped. After many hours of hard labor, the head was driven past the promontory, and then the vertex rotated anteriorly to the first position. Thereafter the child was soon delivered. It weighed seven pounds, was dead, and had the left temple denuded of its cuticle, at a point on a level with the small anterior inferior fontanelle (Casserius's fontanelle). At the autopsy, four fissures were found; one on the left side of the coronal suture (on the frontal bone), and three on the parietal bone. In the same journal, Carus reports an analogous case, in which there was a furrow of the parietal and a fracture of the frontal bone. Schöller, of Berlin,[7] relates a unique case of labor in a primipara with a narrow pelvis. At the end of three days the woman was delivered of a living child. "In the middle of the left parietal, and in the neighborhood of the left temple, the skin was abraded and the bone depressed." "The bone beneath died, and a portion as large as a sixpence of the whole thickness of the parietal bone exfoliated, leaving the dura mater exposed. The destruction of the frontal bone was less considerable." The Transactions of the Medical Society of Erlangen contain the history of a case of spontaneous delivery in a narrow pelvis, reported by W. J. Schmidt.[8] The child was still; its skull had a fracture and a depression on the left frontal region. In the same paper analogous examples are given by H. A. Hirt and Jörg. Another case of natural labor, in a pelvis measuring

about three inches, is given by Osiander.[1] After the most violent expulsive pains a dead child, weighing six and a half pounds, was born, with fracture of the left parietal and frontal bones. Danyau, whose excellent paper[2] has furnished me with some of these references, gives the following remarkable history of a woman whose pelvis was found after death to measure 2.75 French inches: Her first child was delivered dead by the forceps. In five succeeding labors each child offered by the breech, and one was born alive. In her seventh and eighth labors the head presented, and the children were born without aid, but dead. In her ninth labor she was brought to the Maternité. The head came first, and for four hours stayed locked at the brim. Its sacral side was then felt suddenly to bend in, and the same pain drove it down to the vulva. The child was dead. Its skull had a deep depression overlapping the left coronal suture, and shelving obliquely backward to the boss. The death of the mother on the fourth day permitted a careful measurement of the pelvic diameters.

Levret[3] writes of a natural labor in a narrow pelvis in which the "face-half" of the head was obliquely furrowed. Antoine Dugés contends,[4] that "The bones of the skull are often fractured with depression by the sacro-vertebral angle of the mother. It is one of the frontal, or, indeed, one of the temporal regions, which is the most ordinary site of these lesions." As a voucher for this statement, he gives an example of a living child born spontaneously, after a labor of thirty-six hours, through a pelvis measuring 3.25 English inches. The occiput presented to the right, and the right temple showed a red and contused furrow.[5] In another case, the left frontal bone was so depressed as to push the corresponding eye nearly out of its socket. Velpeau declares,[6] that "the depression of the parietal or of the frontal, with or without fracture, has been observed at the Maternité of Paris." Budin, a most careful observer, met with a case of spontaneous delivery in a flat pelvis measuring about 3.4 English inches in its conjugate.[7] The occiput presented to the left, and a small living child was born twenty hours after the rupture of the membranes. On the left frontal region it had a deep furrow, which started from the coronal suture at the anterior fontanelle, and ran obliquely backward toward the base of the skull. Chailly-Honoré holds[8] that "The depressions of the skull have their site ordinarily on the frontal or the parietal bones," and are often the result of natural labor in a reniform pelvis. Casper, after giving a list of writers on this subject, whose works are unfortunately beyond my reach, says that the skull-fractures caused by unaided labor are commonly on the parietal bone "and usually *transversely* to the sagittal suture." Sometimes they are found "stretching from the frontal bone more or less parallel to the sagittal suture."[9] From these citations, it follows that the site of the bone-lesions caused by a natural head-first labor in a flat pelvis, is found, not at one of the poles of the biparietal diameter, but either directly over the

track of the coronal suture, or on either side of it, and generally parallel to it, and at *right angles* to the sagittal suture.[1]

After turning in a flat pelvis, or in one narrowed mainly in its conjugate diameter, a very analogous cranial mechanism takes place. The partial extension of the wedge-shaped head throws the biparietal diameter to one side of the promontory, and places in the conjugate of the brim the small bisauricular (bimastoid) diameter—viz., that portion of each temporal region lying directly in front of the ear. Now, upon traction, if the occipito-frontal diameter of the head be short, or the occipital portion of the pelvis roomy, the head will pass in the transverse (bis-iliac) diameter of the brim, and in a state midway between flexion and extension, while the transit-furrow will be vertical, running directly upward from the smaller bisauricular diameter to the larger bitemporal diameter, close to and parallel to the coronal suture. If the head be large or the brim shortened in its transverse diameter, the resistance to the descent of the hind-head tends to bring about two movements; the one of flexion, and the other of occipito-frontal displacement towards the forehead side of the pelvis. The head should, therefore, pass in the resultant of these forces and of traction; viz., in a line running somewhat obliquely from the front of the ear, or from the anterior inferior angle of the parietal bone, to the vault posteriorly. But this transit-line is more vertical than in the given case of unaided head-first labor, being very generally found very near and almost parallel to the coronal suture, sometimes indeed in the very gutter of this suture-track. For the sacral side of the head being, under traction and propulsion, quickly bent in and fixed by the promontory, resists occipito-frontal displacement; while free lateral bulging at uncompressed points prevents any exaggerated lengthening out of the occipito-frontal diameter. Furthermore, suprapubic propulsion together with two movements of unremitting traction, first in the axis of the outlet and then in that of the inlet, cants the base of the skull over the edge of the promontory, causes its sacral side to be nipped high up, and makes its pubic side revolve around the promontory as a centre of motion, and descend over the glib under-surface of the pubis; in other words the head is, as I have elsewhere expressed it, warped around the promontory.[2]

Now, since this mechanism of a head-last labor in a narrow pelvis is yet mooted, I shall try to prove it by such clinical histories as note the site of the pressure-furrow. Smellie,[3] after turning in a narrow pelvis, and making traction on the child's body "with all my strength," delivered a living child, which did well, although it had "a depression of the temporal bone *before* the ear, and the frontal and parietal bones pushed outwards." Madame Lachapelle[4] advises turning in narrow pelves in

[1] In order to facilitate the work of others in this direction, I append the following references to papers on fractures of the fœtal cranium, which I have not been able to consult: Procés verbal de la distribution des prix, June 20, p. 64, et seq.; London Medical and Surgical Journal, March, 1834, p. 145; Charles West, in Medico-Chirurgical Transactions, 2d series, vol. x. 1845, p. 404; Siebold's Journal für Geburtshülfe, 1825, B. v. S. 224, B. xi. S. 400; C. F. Hedinger, über die Knochenverletzungen bei Neugebornen in Med.-gericht Hinsicht, Leipzig, 1833. The following authors have also written on the same subject: Chaussier, Meissner, Siegel, Ollivier, D'Angers, Viardel, Haller, Bosc, Berchols, Deventer, Dionis, Roederer, Baudelocque, and Stein.

[4] Pratique des Accouchements, Paris, 1825, Eleventh Memoir, p. 429.

order to make the head descend midway between flexion and extension, so as to get the "temporo-auricular diameter" in the conjugate. From several cases of head-last labor in narrow pelves, which she narrates, I select the following: Case I.[1] Primipara; conjugate 2.75 French inches; vertex presentation; forceps slipped; prolapse of the cord; version; head extracted with difficulty and with a sudden jerk (*secousse brusque*). A large girl was born alive, but did not live long. The head had a deep depression on the left frontal bone. Case II.[2] Second position of breech; conjugate 2.5 French inches; child weighed five pounds and had been dead for some time. The head had "a deep depression of the right parietal in its anterior portion and near the temple, caused by the sacral promontory." Case III.[3] First position of breech; "For more than ten minutes the head resisted the most violent tractions" (*aux efforts les plus violens*). Child did well for twenty-four hours and then died in convulsions, from the cranial lesions. An autopsy revealed the separation of the right parietal bone from the temporal along its whole inferior border.

J. J. Phillips[4] reports three cases of successful version in contracted pelves after failure with the forceps. In one of them the child had a "marked depression on the left parietal and frontal bones." Here the transit-line followed the course of the coronal suture. Carl Ruge[5] gives six cases of fracture of the frontal bone, and one along the temporo-parietal suture, after version. In the seven of my own cases[6] in which the pressure-furrow is noted, the site was near or on the coronal suture. The late Prof. E. Martin, of Berlin, says[7] that, after version, "These impressions or depressions of the respective parietal bone are *always* to be found upon its anterior portion, more or less near the coronal suture." Dr. R. Barnes avers[8] that "The mark of pressure or indentation against the jutting promontory is *always* seen at one end of this short diameter:" viz., the bitemporo-frontal. Dr. I. E. Taylor, of New York, in describing a case of labor in a pelvis measuring 2.5 inches in its conjugate diameter, states that "By version and propulsion from above the pubes, the head was flattened or indented at the junction of the parietal and frontal bones, which is the usual place."[9] Many other examples could be cited, but further evidence is needless.

From this mechanism it is clear that version closely imitates the processes of nature, for by it the head enters and passes the conjugate by its shortest diameter, where four yielding bones meet; where four wide sutures converge; where the fontanelle is large and always open; where overlapping is most free, and where compressibility is greatest. Since the resistance is limited mainly to the margin of the brim, that once passed (and generally with a well-marked jerk), there is usually no further obstacle to the descent of the head. It is now brought into relation with new pelvic diameters, and the greater friction of the broader and harder surface of the hind-head brings about the needful movements of flexion and of rotation. To effect this the line of traction must be changed to that of Carus's curve, and finally to one at right angles to the mother's body.

But there are mechanical advantages which turning possesses over a cephalic presentation in a narrow pelvis. Outside help, that of traction and of propulsion, can be invoked without in the slightest degree interfering with th natural mechanism. Again—and this must not be overlooked—by turning, the head enters the brim by the very short bis-auricular (bimastoid) diameter of its base, and passes the conjugate by the larger but more compressible bitemporal diameter of its vault; that is to say, the small end of the wedge is first nipped. In the corresponding head-first labor, the reverse to this takes place; for the head enters the conjugate by its bitemporal, or the vault portion of its bicoronal diameter. From repeated measurements taken shortly after birth, I find that the average length of the bisauricular diameter is 2.6 inches, and that of the bitemporal diameter 3 inches—a difference of nearly half an inch.

From this description of the cranial movements, it follows that turning should be limited to cases of antero-posterior shortening of the brim. For, in other kinds of narrowing, the previously described mechanism, so essential to success, could not take place. In the generally and uniformly narrowed pelvis, the transverse (bisiliac) diameter of the brim would probably be too short to permit the after-coming head to pass in a state midway between flexion and extension; while, on the other hand, if the head were forcibly flexed, a longer diameter than the bitemporal would be jammed into the short diameter of the brim. Again, from the narrowing of all the diameters of the whole pelvis—brim, bony canal, and outlet—the after-coming head would be detained at every stage of its descent, and could not, therefore, be delivered soon enough to avert fatal asphyxia. To save the life of the child, then, the forceps, and not turning, is here needed. As a corollary to this, less power and time are needed after version to deliver an average head in a flat pelvis, than a large head in an average pelvis; for, in the former, the resistance is marginal, and limited to a single osseous point; in the latter, diffused more or less, not only over the whole bony brim, but over the pelvic canal and outlet.

How to tell a uniformly narrowed pelvis from one narrowed mainly in its short diameter, becomes, then, an important question. Apart from careful digital examinations, much may be learned from measuring the distance between the anterior-superior spinous processes and that between the crests of the ilia. In a standard pelvis these distances average respectively 25 cent. (9.8 inches) and 28 cent. (11 inches).[1] But what should mostly be relied on is the position of the head. When conjugate narrowing alone exists, or when it preponderates, the occipito-frontal diameter lies parallel to the transverse diameter of the brim, with the anterior fontanelle low down. A head so situated implies conjugate narrowing and transverse amplitude of the brim. When the pelvis is uniformly narrowed, or when transverse (bisiliac) narrowing preponderates, the head will be found high up and very strongly flexed. This happens because the resistance at the brim is equal on all sides, and the shorter arm of the occipito-frontal lever must therefore descend. The sagittal suture, for the same reason as in a standard pelvis, will be found running more obliquely than transversely. Such cranial conditions show that the transverse diameter of the brim is too short to admit the occipito-

[1] Carl Martin, Monats. für Geburtsk., Dec. 1867.

frontal diameter of the head, and that version is consequently inadmissible.

Turn now to the mechanism of labor when the forceps is used at the brim of a flat pelvis. If the blades are applied to the fronto-occipital, or to the fronto-mastoid diameter, the head, which is lying midway between flexion and extension, is—unless firmly nipped in the conjugate—forcibly flexed, and either the biparietal diameter, or some diameter longer than the bitemporal, is made to enter the short diameter of the brim. Again, the fronto-occipital compression to which the head is subjected, not only prevents the natural lengthening out of the long diameters, but it causes bulging of all the cross diameters. This is, of course, a mechanical disadvantage, one which increases the difficulty of the head's transit, and which can be overcome simply by a brute tractile force—such as puts fœtal life in jeopardy. In addition, the fronto-mastoid application tends to force a premature anterior rotation of the hind-head. Also, the line of traction on the forceps-handles will invariably be at an angle to the axis of the superior strait, and the brunt of the traction is wasted on the pubis. Finally, such an application, by flexing the head or by shortening its fronto-occipital diameter, so widens the iliac spaces that prolapse of the cord is very liable to occur. "Statistics show that out of five applications of the forceps above the superior strait, no fewer than two are complicated by a prolapse of the cord. I," continues Chailly-Honoré, "have met with it in the ratio of twice in three cases."[1]

On the other hand, when the blades are applied along the sides of a head at the brim of a narrow pelvis and lying in its transverse (bisiliac) diameter, flexion is inevitable.[2] So essential, indeed, is this movement for the accurate adjustment of the blades, that some practitioners try

[1] Accouchements, 1867, p. 643.

[2] The statement often appears in foreign medical works, that this application is impracticable whenever the head lies in the transverse diameter of the brim. This is a mistake; for, although the long curved forceps then becomes virtually a straight one in so far as the pelvic curve is concerned, this application can be very generally made with a properly constructed instrument, provided the head be not locked. With the Hodge or the Davis forceps I have frequently made this application, and have repeatedly seen others make it. Hodge and Meigs, it is true, condemned it; but they denied, not its practicability but, its advisability. Baudelocque, Capuron, and Gardien, warmly advocated it, and it is now the habitual practice of some of the best obstetricians of Philadelphia. It possesses the great merits of securing the firmest grip, of compressing the head in its least vulnerable diameter, and of lessening the pressure on the bladder. Since the mode of making this application is peculiar, a description of it may not come amiss. If the occiput look directly to the left ilium—and this is the most common cephalic position in the simple flat pelvis—the woman is turned over on her back, and her coccyx made to project over the edge of the bed. The right (female) branch is first introduced in the right side of the pelvis, with the convex surface of its blade looking obliquely to the sacrum. By a rapid downward sweep and a spiral twist of its handle, together with upward pressure on the convex edge of its blade by the fingers in the vagina, it is rotated very nearly half of a circle over the forehead to the side of the child's head under the pubis. The left (male) branch is now so held at its lower convex edge by the tips of the fingers of the right hand, that its handle hangs down. While held in this position, the blade is introduced, as far as it can be made to go, in the right side also of the pelvis, over the child's left temple but under the shank of the female blade. The right hand is next carried to the still pendent handle, which it raises, and upon which it makes upward pressure. This movement, combined with a guiding pressure from the fingers of the left hand in the vagina, makes the blade glide up over the sacral side of the head. When the branches are united, the lock should press firmly on the tuberosity of the left ischium. Should the occiput look to the right ilium, the same general rules are to be observed. But now both blades are to be introduced in the *left* side of the pelvis—the left (male) blade first, and under the pubis; the right (female) with its handle pendent. The lock should now press firmly on the tuberosity of the right ischium.

first to flex the head, either by the hand, by the vectis, or by one blade of the forceps. In my own experience, however, the act of locking and that of grasping the handles, usually bring about the needful amount of flexion ; for success in such an application of the forceps presupposes a certain amount of mobility of the head, which insures its flexion.

Hence the large biparietal diameter, or one of its congeners, must inevitably pass directly through the narrow conjugate. But, apart from its width, the hind-head is the least compressible portion of the cranium. The parietal bosses, being projections, as their name indicates, and being also the centres of ossification, are the most unyielding points of the vault. They are in fact eburnaceous when compared with other portions of the parietal bones. The posterior fontanelle is small, not open, and not infrequently ossified. The sutures are narrow. Only three bones meet there, the occipital and the two parietals. But the occipital bone goes to form the hard cranial base, and is incompressible. The compressibility of the hind-head is therefore limited to the equitation of the parietal bones. But being shored up and buttressed by the unyielding occipital bone underneath them, they cannot readily overlap or bend in. Hence the tedious traction needed for forceps-deliveries, when compared with that required after turning. Transit-furrows are rare, but, when present, they run anteriorly from the boss either obliquely toward the cranial base, or parallel to the sagittal suture. In a recent case of forceps-delivery this was very strikingly shown. The diagonal conjugate, measured by the rule and finger, gave a length of four inches. The sagittal suture ran transversely to the left ilium, with the large fontanelle dipping down so low as to make it almost the presenting part. The blades of the forceps were applied to the sides of the head, which flexed on bringing the handles together. After strong traction of about two hours' duration, made alternately by the attending physician and myself, the head was finally delivered. It was much flattened, and presented on its sacral side the well-marked furrow of a fracture running from the parietal bone obliquely to the mastoid process *behind* the ear. The child was still; the mother died four days afterwards from peritonitis, and I now regret not to have turned. Dugés[1] also describes such a fracture of the parietal boss in one of his forceps cases. Fractures and furrows at this site would far more frequently happen in instrumental labor, were it not that the hard boss so resists the direct pressure upon it as either to flatten the whole parietal bone, or to cause lesions of it at weaker, although unimplicated, points.

But there are mechanical objections still stronger against the forceps when compared with version. The base of the skull being unyielding, the head cannot be compressed so readily by catching the vault with the forceps. For the effect is then to direct the compressive power toward the unyielding base. But by turning, the compressive power is directed toward the yielding vault. Further, from the peculiarity of construction of the forceps, the compression exerted by it is necessarily diffused over the whole surface covered by the blades. Now, in a bilateral application, the tips of the blades cover the bones of the cheeks, which are incompressible and so narrow as to need no compression whatever. Hence, not only is this amount of compressive power misapplied and sheer waste, but it detracts by so much from that applied to the offending diameter—the biparietal. Thus the surface covered by the blades not only involves

[1] Manuel d'Obstétrique; Montpellier, 1840, part v. sect. i. art. i. p. 306.

unimplicated diameters, but it is too broad to be very materially reduced by compression. Even when the handles are lashed, but little more is gained, and that little at the expense of a prolonged, disorganizing pressure upon the brain. Baudelocque's exceptionally powerful forceps were, with lashed handles, found by their inventor barely to reduce the biparietal diameter as much as four lines, although the force applied was so great and so prolonged as to spoil the three instruments used. It follows, therefore, that the Hodge or the Davis forceps, which are much feebler instruments than the French one, cannot compress the biparietal diameter as much as three lines, and the operator is therefore compelled in narrow pelves to make the anterior portion of the brim and the promontory of the sacrum do most of the compressing work; and that by sheer and prolonged dragging force, which, as in the case just narrated, threatens injury to the mother and death to the child.

Again, the forceps-blades being of equal length and breadth, and being also applied to corresponding surfaces of the child's head, make equal compression upon the pubic and the sacral side of the head. But from the limitation of the bone-lesion in these pelves to the posterior half of the brim, the pubic side of the head needs no compression; for its convexity naturally adapts itself to the smooth concavity of the anterior half of the brim. Therefore just one-half of the effective compressive power is absolutely thrown away. For granting that, in a given case of conjugate narrowing, the forceps reduces the biparietal diameter by three lines, this diminution does not facilitate to the same extent the passage of the head; for supposing that it actually reduces the width of the head by three lines, yet it does not virtually so reduce it. This is evident from the fact that the pubic side of the head needs, not compression, but adaptation, and the bulging tissues around the periphery of the blades will at points separated by their width still impinge on the pubic concavity of the brim, making the clamped portion of the head subtend the symphysis pubis like the chord of an arc. In all the narrow pelves belonging to the museum of the Philadelphia Obstetrical Society, and one of them is under two inches in its conjugate diameter, the pubic side is concave and smooth. After a careful examination of the distorted pelves in the museum of the University of Pennsylvania, I find that the same condition obtains in all that were not affected by osteomalacia. Turn now to the sacral blade of the forceps; it is the posterior half of the brim which is distorted; and to its irregular configuration must the sacral side alone of the head be moulded. Since also the distortion is mainly owing to the descent of the sacrum as a whole, and to the anterior projection of its promontory, the portion of the head needing moulding is a small area of surface corresponding with the sacro-vertebral angle. In other words, it is, when flexion is forced by the forceps, the biparietal diameter alone that needs shortening, and that by the indentation of its sacral pole. But the very width and length of the sacral blade thwarts this indication. This blade flattens the whole sacral surface of the head, but does not mould it. The whole head and included brain are in fact flattened out by the two blades. And this excessive bilateral compression so unnecessarily lengthens out all the other diameters of the head, that every physician has seen forehead bulging out, eyeballs starting from their sockets, and life destroyed by the violent and prolonged compression to which the whole brain has been subjected. In one word, by the bilateral compression of the forceps the pubic blade interferes with the process of adaptation; the sacral blade prevents the utilization of the roomy

concavities on each side of the promontory, and the whole brain is, therefore, subjected to an unnecessary amount of compression.

The catch-word "moulding," which is so much used to designate the action of the forceps, is a misnomer. Moulding here means an outline conformity of the cranium to the kidney-shaped configuration of the brim. To attain this end, it is needful for the pubic side of the head to adapt itself to the smooth concavity of that portion of the pelvis, for the occipito-frontal diameter to be moderately lengthened out, for a limited area of the sacral side of the head to be bent in by the promontory, and for lateral bulging to take place around it in the very roomy sacro-iliac spaces. No moulding of the head, in its true obstetric sense, can possibly occur, unless, as in natural labors or by version, the pelvis itself acts the part of the moulder. Look at a head in the grasp of the forceps applied bilaterally. How is it possible for this steel-ribbed head to alter its shape to that of the brim? How can any bending-in take place within the fenestra of the sacral blade, whose iron rim, by firm pressure, acts as an abutment to the included parietal boss? How can the pubic side of the head adapt itself to the anterior portion of the pelvis? How can the head bulge out at points clamped by iron? The forceps, thus applied, indeed moulds the head, but to its own shape, and not to that of the brim. For how can bow-shaped blades mould a head to a kidney-shaped brim? The thing is an impossibility. Who ever saw a head kidney-shaped which had been delivered in such a manner through a narrow brim? The truth is that the head then passes the brim by being flattened out, and not by being moulded; and, what is worse, since the blades do not exert the needful compressive power, the promontory itself is made to do most of this unnatural work—the work of flattening and not of moulding. When the head is squeezed sufficiently flat, it is delivered by being dragged straight past the promontory, without revolving around it as it does in natural or in version cases.

So true is this that, when a head has been delivered through a small conjugate by the forceps applied bilaterally, never will it exhibit a cast of the promontory by a spoon-shaped depression, and only once have I seen a slight furrow. The whole head is flattened, the bones are separated at the sutures, sometimes so much so as to seem loose in a scalp-bag, but no lesion of limited area is found by a surface examination. Post-mortem examination will, however, reveal fissures and fractures radiating from the base of the parietal boss.

It follows that the hackneyed term of "wire-drawing" the head by the forceps, is also a misnomer. In "wire-drawing," the pincers which seize the end of the wire do not pass through the graduated holes in the draw-plate, but work outside of them. But when the head is seized by the forceps, the pincers, so to speak, must also pass through the bony draw-plate itself. So great a disadvantage is this, that there are on record far more remarkable cases of successful natural delivery in very small pelves, than there are by this use of the forceps. For it stands to reason that when a forceps, whose blades lie from two and three-quarters to three inches apart, is applied to the sides of a head at the brim of a pelvis with a conjugate of less width, the blades will need wire-drawing as much as the head, before they can be made to pass.

So far the use of the forceps. Mark now what happens when the child is turned in a flat pelvis. The wedge-shaped and semiflexed head enters the conjugate by its small bisauricular diameter, and passes it by

its very compressible bitemporal diameter. The very cause of the conjugate deficiency—the jutting promontory—becomes itself the moulder, and the plastic head, unhampered, unclamped, unribbed by bars of steel, being also drawn upon by *outside* traction, accurately moulds itself to the shape of this small bony barrier. Meantime the pubic side of the head, already presenting its convexity to a concavity, is made by lateral pressure to fit snugly the anterior half of the brim. Bulging takes place at all the uncompressed points, and the whole head becomes concavo-convex, being rapidly moulded to the kidney-shaped configuration of the whole brim, while backward traction and supra-pubic propulsion cause the pubic side to revolve around the promontory as a centre of motion. To my mind nothing can be plainer. How, otherwise, is the absence of vesical disturbance, after version, explainable? How the fact that, as I have seen and others attest, it will take as many minutes, less minutes indeed, to deliver the head by version, as it has taken hours of unsuccessful traction with the forceps? Even without these facts and without a cloud of witnesses to sustain them, an *à priori* reasoning would compel me logically to the inevitable conclusion that version possesses great mechanical advantages over the forceps.

One word in regard to the obliquely ovate pelvis. If the hind-head present in the less roomy side, by turning, the soft and voluminous breech is very likely to adapt itself and pass through the more roomy side. This tendency, together with a knowledge of the fact that the foot drawn on usually rotates to the pubic arch, ought, very generally, to enable the practitioner to place the occiput in the larger half. Yet so great an advantage is it to turn, that Barnes and Strassmann declare[1] that they have saved the children, even when they had failed by this operation to effect the desired change of position.

The use of the vectis, or tractor, in narrow pelves has been so highly lauded by Boddaert, of Brussels, Raffaele, of Naples, Fabbri, of Bologna, Marchant, Herbiniaux, Coppée, Beytter, Frayes, and other Dutch, Belgian, and Italian writers,[2] that a few words in regard to the action of this instrument are needed.

When the head is transverse, this instrument should be passed over the pubic mastoid region; when oblique and anterior, over the pubic side of the occiput; and when oblique and posterior, over the pubic fronto-temporal region. At first it is used as a lever of the "first kind," the left hand on the shank representing the fulcrum, and the right hand becoming the power by raising the handle toward the pubes. In other words, each hand acts in opposite directions—the left one mainly to protect the pubis from pressure. As soon as the handle is raised high enough for the blade to secure a good hold, the right hand is kept at rest to become the fulcrum of a lever of the "third kind," while the left acts as the power. This compound action of traction and leverage, peculiar alone to the vectis, here meets several important indications. As a lever, this instrument compresses the head from before backward in its lateral diameter, and aids the moulding of its free sacral surface to the posterior distortion of the brim. By its action as a tractor, it hooks down the pubic side of the head, making it revolve around the promontory of the sacrum as a centre of motion, and roll over into the pelvic cavity.

[1] Obstetric Operations; by R. Barnes, 1871, chapter xvi. p. 241.

[2] Cazeaux, edited by Tarnier, 1874, p. 998; Congrés Médical de France, 1865, pp. 584, 589; Traité des Accouch., par Hyernaux; Bruxelles, 1866, p. 699; New Sydenham Society's Biennial Retrospect, 1869–1870, p. 409.

From the close resemblance of this mechanism to that of an unaided head-first labor, and to that of an aided head-last labor, I am led to think that the vectis, in skilled hands, will be found more efficient than the forceps in dislodging a head from the brim of a pelvis narrowed mainly in its conjugate diameter. Below the brim, and in the generally narrowed pelvis, it cannot of course compete with the forceps excepting in certain anomalous positions and presentations. But in selected cases this neglected single-bladed instrument is, in my opinion, destined to take rank over its double-bladed fellow. For instance, in 1863, the late lamented Fabbri, of the University of Bologna, quickly delivered with the vectis, through an artificial pelvis, a head which S. Tarnier,[1] although using all his strength, was not able to budge with the forceps. The head was then replaced, and the forceps re-applied, but with the same want of success. Professor Tarnier, who is the narrator, then resorted to the lever, and, much to his surprise, delivered the head "with astonishing ease" (*avec une étonnante facilité*). This experiment was repeated, and invariably with the same result.

To sum up then the mechanism of natural and of artificial labor in a flat pelvis:—Nature makes the first-coming and the after-coming head enter the brim by extension; the forceps by flexion. With the former the head engages in the short conjugate by its shortest and most compressible diameter; with the latter by its largest and most unyielding diameter. By nature and by version the head revolves around the promontory as a centre of motion; by the forceps it is dragged straight past, over this osseous point. By the former the head is moulded to the outline configuration of the brim; by the latter, when applied to the biparietal diameter, it is moulded more to the shape of the blades than to that of the brim. By the one the brain lesion is local and limited to the area bent in by the promontory; by the other the area of undue compression is increased. By nature and by version the compression is that which is needed and no more; by the forceps it is more than is needed.

Regarding then alone the mechanism of labor in narrow pelves, to which the scope of this paper is strictly limited, the following conclusions are reached:—

I. The unaided first-coming head and the aided after-coming head observe in a flat pelvis precisely the same general laws of engagement and of descent. Hence, version here means art *plus* nature.

II. The forceps, however applied in a flat pelvis, antagonizes more or less with the natural mechanism of labor. Hence, the forceps here means art *versus* nature.

III. The aided and the unaided first-coming head observe in a uniformly narrowed pelvis precisely the same laws of engagement and of descent. But version violates these laws. Hence, the forceps here means art *plus* nature; version, art *versus* nature.

IV. At or above the brim of a flat pelvis, the fronto-mastoid or even the fronto-occipital application of the forceps interferes less with the moulding of the head, and violates less the natural mechanism of labor, than the biparietal application.

V. In the flat pelvis, the vectis aids the natural mechanism of labor, and, therefore, meets the indications better than the forceps.

[1] Cazeaux's Obstetrics, 1874, p. 996.

Discussion on Dr Goodell's Paper.

After the reading of the preceding paper, the President, Dr. Robert Barnes, of London, said:—The paper is now open for discussion. I desire, however, first to say that it is the ablest paper that I have ever heard or read upon the subject. I am aware of the difficulty in treating this question, for the passage of the fœtus through the pelvis, and the obstructions to its progress from deformities, are not only to be studied clinically, but, as the conditions are mechanical, by *à priori* reasoning. Yet, after all, experience is the best guide, whether the method proposed is clinical or empirical. I shall be glad to hear from the members of the Section, and may suggest as heads for the discussion (1) the mechanism of labor when unaided, and (2) its mechanism when aided by art. I am glad to see in the room Prof. Barker, who has possibly more special knowledge on this subject than any one I know of.

Dr. Fordyce Barker, of New York, said:—I believe that Obstetrics has begun to make itself an exact science, and I am sure that investigation and the presentation of papers such as we have heard will have a tendency to make it more and more exact. I am sorry that I did not hear the first part of the paper, for I should feel like studying it carefully before commenting upon it. I think that the vectis in certain cases of contracted pelves is preferable to the forceps, and I am pleased to find that Dr. Goodell agrees with me upon this point.

Dr. William H. Byford, of Chicago, said:—I have greatly enjoyed the reading of Dr. Goodell's paper, but as to criticism, I think mine would be valueless. I have in my writings advised the use of the vectis in cases of the after-coming head, where it has not entered the pelvis; but I use the forceps where the head is fully in the pelvis. Since hearing Dr. Goodell's paper, I feel disposed, in the case of kidney-shaped pelves, not only to turn, but to use the vectis instead of other instruments. Obstetrics is a science that is almost entirely mechanical, and for that reason I think, with Dr. Barker, that it will ere long become an exact science. I regret very much that I have not had the time or the opportunity to study the valuable paper which has been presented, and the subjects treated of in it.

The President, Dr. Barnes, said:—It must be apparent that in certain cases of narrow pelves one must resort to the induction of premature labor; but that point has not been referred to. The value of this operation has been called in question of late years, and it may be well to inquire how does the mechanism of labor bear upon those cases in which lives are thus saved? I should like to have the experience of those familiar with cases in which the child has lived after the induction of labor.

Dr. William Lusk, of New York, said:—In the main I agree with the conclusions of Dr. Goodell. I have, however, applied the forceps along the sides of the pelvis, and have, in some cases, dragged the head down to the floor of the pelvis, without flexing it, both fontanelles being nearly on a level. It has always been my habit, after the conjugate diameter has been passed, to wait for the head to flex and the occiput to rotate, before renewing traction and completing the delivery. If continuous traction be kept up, then all the statements of the paper are justified; but if occipito-frontal compression be applied at the brim, and traction made only during the pains, the child's head will generally pass without being flexed, and delivery will be effected in accordance with the mechanism described by Dr. Goodell. When the head is fixed in the brim, I would use the forceps with no apprehension of flexing it.

Dr. Goodell, in reply to a question, said:—I have no experience with the instrument of Chassagny. But all the distinguished obstetricians in France are leaning in the very questionable direction of importing the labor-saving instruments, the straps, pulleys, and capstans, of veterinary obstetrics, into human obstetrics. In 1872, Chassagny bore off the Montyon prize for his

appareils de traction soutenue, and since then many others have been invented. It is a significant fact that these instruments have originated in France, where version is bitterly opposed. It is also a significant fact that the only eminent French obstetricians who oppose them are Blot, who practises version to save the life of the child in narrow pelves, and Pajot, who turns in order to crush the base of the skull by his cephalotribe.

Dr. Alexander R. Simpson, of Edinburgh, said:—The flat pelvis presents peculiar advantages for version. One would expect the greatest advantage when the base of the skull, which is the narrowest part, comes in relation to the narrowest part of the pelvis. I have seen this, in my own practice, again and again. Reference has been made to Budin and his series of mechanical experiments on the comparative force needed by version and by the forceps in dragging the child through the pelvis. These experiments have somewhat staggered me. In some of them the long diameters were shortened, and in others they were elongated. In Dr. Goodell's conclusions I see allusions made to the application of the forceps to the sides of the head at the brim. But it is an impossibility for the forceps to grasp the sides of the head in the case of a flattened pelvis; for there is no room, and the operation is simply impracticable. It might be possible for one blade of the forceps passed over the occiput and the other over the forehead to so grasp the head as to produce elongation and thus cause the head to pass through a narrow brim, but version is preferable in these cases.

The President, Dr. Barnes, said:—I have practised version for twenty years in preference to using the forceps, and am becoming more partial to it the more I practise it. From the forceps there can be but little benefit except in minor contractions, but in great contractions, where there is any chance of saving the child, I should use all means in preference to the forceps. As to the mechanism of labor in a "head-first presentation," it has been well explained in the paper of Dr. Goodell. I can only add force to those deductions by referring to the frequency of occipito-posterior positions in contracted pelves, a frequency which enforces Dr. Goodell's arguments. Under such circumstances version is the best mode of delivery, but there are occipito-posterior presentations in which, the head having passed through the narrow brim, and the woman being exhausted, the forceps will finish the labor. I have delivered one lady five times, all with the same difficulty of occipito-posterior presentation. In another case in which there was a slight contraction of the pelvis, the child was lost by the use of the forceps, but on two occasions when I turned, the child was saved. It requires practice in these cases of version in a narrow pelvis, and the mechanism, in head-last presentation, will be much better understood by careful study. In turning, there is the danger from dragging on the child's neck, and from the traction on the medulla oblongata, or in some cases from the injury to the brain pulp. I have seen a child's head pulled off by injudicious traction. There is in these cases often a misdirection of force on the part of the physician which jeopardizes the child's life.

[Dr. Barnes explained by a diagram on the blackboard the method of getting the head around the sacral promontory by backward traction.]

The force needed can be augmented, and the mechanism facilitated if some one pushes from above while the physician pulls from below, as this will take off a great deal of the strain on the neck, and the propelling hand can guide the child's head in its rotation around the promontory. I lay great stress on supra-pubic propulsion by the hands of an assistant. The use of forceps on the fore-coming head in contracted pelves, is not based upon sound mechanical principles. In cases of minor contraction, it aids delivery by elongating the head. The direction of thought in obstetrics is now tending to a greater precision in this question of the mechanism of delivery. Sometimes it is found impossible by any mode of delivery to save the child alive; sometimes the woman is too much exhausted for an attempt at version to be made. In these

cases, after perforation and the escape of a few ounces of brain, the forceps can be used for breaking the skull from behind, and it will be found to collapse at once. It cannot be said under such circumstances that the child has been sacrificed, but that all endeavors to save the life of the mother have been used, and that the child has been abandoned only when it has become absolutely necessary. As to the vectis, I deem it of service only in cases of minor contraction; but it has been greatly lauded by some provincial practitioners, who prefer it to the forceps.

Dr. GOODELL, in reply, said:—I was glad to hear Prof. Simpson refer to M. Budin's paper. Its conclusions in favor of the forceps at first staggered me also, but, upon an examination of the experiments, three sources of fallacy became manifest. In the first place, the pelvis used by M. Budin was not an originally flat one, but an iron cast of what was supposed to be a normal pelvis. To narrow the conjugate of this metallic pelvis, Budin had a movable, false promontory so constructed that a sacral screw forced it towards the pubis. Hence the conjugate diameter of the brim was shortened without a proportional lengthening out of the transverse diameter, and every turn of the screw converted the pelvis into a uniformly narrowed, flat pelvis, and not into a simple, flat one. Thus, as his experiments abundantly showed, there was not room enough in the transverse diameter of the brim to admit the occipito-frontal diameter of the head. But when he experimented with children born before term, and consequently with a shorter occipito-frontal diameter, far less tractive-force was needed to deliver them by turning, than by the use of the forceps. Again, this movable and metallic, false promontory was cast from a mould taken from the broad, blunt, and rounded promontory of a normal pelvis, and not from the narrow, sharp, and jutting promontory of a flat pelvis. Hence the needful indentation of the head was gained by this broad and blunt knob of a promontory with very great difficulty. In the third place, Budin's iron pelvis was placed on a table and near its edge, to represent the dorsal decubitus of a woman when artificially delivered, while the tackle used by him for these experiments was fastened to a staple driven, not into the floor near the legs of the table, but into the wall. Consequently, not only no backward traction could be made on the legs of the child, but the traction was so directed as to cause the head to revolve around the pubis, and not around the promontory, as the centre of motion. In reply to Dr. Lusk I would say that, if the head be well nipped in the conjugate, the fronto-mastoid or the fronto-occipital application of the forceps will not ordinarily flex it. But in other cases it commonly flexes the head, and always tends to do so. When the blades are applied to the sides of the head, the vertex always dips, and the biparietal diameter enters the conjugate, because such an application could not be made if the head were tightly nipped. I wish finally not to be misunderstood as recommending version to the exclusion of the forceps. The forceps is for obvious reasons generally my first choice; besides, version cannot always be made; in some cases, indeed, should not be attempted. But in the paper which I have read, I have avoided all such side-issues, and have approached the subject from a purely mechanical stand-point.

THE MANAGEMENT OF CONVULSIONS, IN CHILDREN, DEPENDING UPON A HIGH TEMPERATURE OF THE BODY.

BY

T. K. HOLMES, M.D.,

OF CHATHAM, ONTARIO, CANADA.

GENTLEMEN:

I purpose, in this short paper, to ask your attention to the management of convulsions, in children, depending upon a high temperature of the body. The subject will not be thought unworthy of consideration by any one who has seen this complication resist various plans of treatment, and prove fatal after hours of intense anxiety on the part of all concerned. The great frequency and fatality of convulsions, in children, should be a strong incentive to all physicians to avail themselves of every mode of reducing the mortality. In this city during the five years from 1844 to 1848 inclusive, 1729 children, under fifteen years of age, died of convulsions; a higher mortality than attended either cholera infantum, marasmus, pneumonia, or hydrocephalus, during the same years. It is neither possible nor desirable in this paper to enter into a lengthened discussion of all the phenomena connected with this subject. This has been done by most modern authors, and by none more lucidly or ably than by your distinguished countrymen, Meigs and Pepper.

It is admitted by all that eclampsia is a frequent complication in many febrile diseases, as scarlatina, measles, pneumonia, malarious fevers, etc., and by nearly all writers great prominence is given to the particular poisoning of the blood in these affections, as the chief factor in the causation of the convulsive fits which so often complicate them. While admitting that certain septicæmic conditions may not be without influence in producing the convulsive attacks, I believe that the simple elevation of temperature, accompanying these diseases, is sufficient, in most cases, to account for them. In this connection it is worthy of note that those febrile diseases in which convulsions are common, are those usually marked by a high degree of temperature, although the specific poison in each may be quite different; and that in other diseases, as smallpox, syphilis, and diphtheria, in which the blood-poisoning is very virulent, but the temperature not very high, convulsive seizures are comparatively rare. The experiments of Dr. Brunton prove that heat acts as a direct excitant to the heart, causing it to beat more frequently, directly as the elevation of temperature, and that cold has the opposite effect. These results are due to the influence of heat and cold upon the cardiac nerves, and from the extreme nervous irritability accompanying fever, as evinced by restlessness and liability to convulsions, it is fair to conclude that heat and cold act similarly on the cerebro-spinal system. While an elevated temperature causes increased frequency in the heart's action, it weakens the force of its contractions, a fact that should not be overlooked in the administration of some therapeutic agents which, however useful under other circumstances, become highly dan-

gerous when the heart has become weakened from any cause. This is especially true of aconite, veratrum viride, chloral hydrate, and bromide of potassium.

From observations upon thirty cases, of which I have preserved notes, the following propositions may be deduced: (1) That the nervous susceptibility of children under ten years of age strongly predisposes them to convulsions; (2) that in children of that age a temperature of 103° Fahr., and upwards, is very liable to excite an attack; (3) that the severity of the attack bears a direct ratio to the intensity of the fever; (4) that convulsions are more liable to occur during the first few hours of the pyrexial seizure, than at any subsequent period of its course; and (5) that whatever reduces the temperature, modifies or arrests the convulsions.

Regarding the first four propositions, few will differ, but while the fifth may be generally admitted, there is great diversity of opinion as to the best manner of accomplishing the reduction of temperature. The means at our disposal may be classed as internal remedies and external applications; the former including veratrum viride, aconite, digitalis, quinine, and salicine, with probably some others not as much used nor as well understood, and the latter consisting of cold applications to the surface of the body. Most of the remedies of the first class exercise a very depressing influence on the heart, and so are not applicable to these cases, quinine being almost the only one upon which any reliance can be safely placed. It generally happens, moreover, that in all severe cases of convulsions the child cannot swallow, and then remedies of the first class must be dispensed with altogether unless we resort to their administration hypodermically, a proceeding not warranted by the results obtained.

For the antipyrexial action of quinine, veratrum viride, aconite, and digitalis, I would refer to the experiments of Dr. Roberts Bartholow, of Cincinnati, which have been published in one of a series of clinical lectures edited by Dr. Seguin, of New York. From a study of the physiological action and therapeutic influence of these remedies, it is plain that their modus operandi, in reducing the temperature, is quite different from that of cold applied to the surface of the body. In the former, the result is accomplished by interrupting the conditions which render rapid chemico-vital change in the capillary system possible; in the latter, it is accomplished by the simple abstraction of heat already generated. By the former, it is accomplished slowly, imperfectly, and with great risk to the patient; by the latter, the same is done rapidly, perfectly, and, in at least the great majority of cases, without risk. It is chiefly with the view of illustrating the curative influence of remedies of the second class that I have ventured to ask your attention even for a few minutes. For this purpose I have transcribed from my case book the following cases:—

Case I.—July 3, 1876. M. Arnold, two years of age, strong and well developed, was taken suddenly ill last evening with dysentery and high fever which lasted all night, and at seven o'clock this morning had a pretty severe convulsion. At eight I saw him for the first time, and found the temperature 103° F., and the child restless. I gave a large dose of castor oil, and also one-third of a drop of tincture of aconite, to be repeated every hour while fever lasted. Another convulsion occurred at ten o'clock, and a third at half-past ten, when I arrived in time to check its violence with chloroform. At noon, the castor oil had operated well. At 2 P.M., convulsions returned, and continued for

two hours with no intermission, although the patient was partially under the influence of chloroform during the time. At 4 P.M. they were as violent as possible, the temperature was 105° F., the pulse 150 and very weak, and death seemed imminent. I now put the child into a tepid bath, and rapidly cooled it to 50° F. by the addition of ice and iced water. At the end of ten minutes the breathing became easier, in fifteen minutes the temperature was 103° F., and in twenty minutes it had fallen to 99° F., and the pulse to 110 beats per minute. I then dried the child and wrapped him in a blanket. He was very much better, but the breathing was still somewhat noisy and labored, and there were two slight fits during the first half hour succeeding the bath; the temperature also began to rise again, and had reached 101° when I again put him into the same cold water for five minutes. The temperature now fell to $98\frac{1}{2}$°, and the pulse in the same time to 100 beats per minute. The child slept naturally for half an hour, and awoke apparently quite well. There was no return of fever, and no further treatment was required.

One can scarcely avoid the conclusion that the convulsions in this case were caused by a high temperature alone. The previously healthy state of the child, the freedom of the alimentary canal from anything irritating, for the castor oil had acted thoroughly two hours before the most violent attack came on, the absence of any other appreciable, centric, exciting cause, and the almost instantaneous cessation of the convulsions when the temperature had fallen below 99°, all support this conclusion.

Case II.—Sept. 26, 1872. P. T., æt. 8 years, was never ill until noon to-day, when he had a chill for a few minutes, followed by fever and convulsions, which still continued when I arrived at one P. M. His temperature was 106°, and his pulse 140, full, and regular. The attendants had just removed him from a warm bath and wrapped him in a blanket. It was impossible to get him to swallow anything. I at once applied cold to the head, administered an enema, and put him under the influence of chloroform. This modified the violence of the spasms, but they returned immediately when the effects of the anæsthetic were allowed to pass off. The enema acted well, and the chloroform was continued, but the temperature was unchanged, the pulse became gradually weaker and more frequent, and after three hours the patient died. As this boy had been well until now, and as no other exciting cause could be traced, it is not unreasonable to conclude that the high temperature led to the fatal result.

Case III.—July 12, 1876, 10 A. M. C. S., a well-nourished male child, five months old, has had diarrhœa for three days, and the mother thinks fever also, but was not very ill until yesterday afternoon, since which time he has neither nursed nor slept, but has constantly uttered half suppressed cries. The child is pale, the hands and feet quite cool, and the skin dry. Gave a purgative dose of rhubarb and soda.

3 P. M. The rhubarb has acted on the bowels three times, the last evacuation having been quite natural in color. The hands, feet, and legs are quite cold; the pulse almost imperceptible; the pupils not larger than pins' heads; the thumbs contracted; the face pinched, and of a leaden hue; and the thirst most intense. The axillary temperature, to my surprise, was 105° F., for I had been deceived by the coldness of the extremities and the general appearance of the patient, and did not expect to find the temperature so high. I now gave the child half a drachm of brandy, and placed it in a tepid bath, adding water from the well until the whole was quite cold. In ten minutes the temperature fell to 103°, and the child went to sleep for the first time in thirty hours. When the temperature had fallen to 100°, I wrapped the child in a blanket, and he continued to sleep most of the afternoon and was not thirsty. As the temperature fell, the pulse became slower and fuller, and the pupils larger.

8 P. M. Temperature 103°, pupils natural; the child sleeps well and looks placid. Bath repeated, and temperature reduced in five minutes to 99°.

13th, 10 A.M. Child rested well all night; nurses; temperature 103°. As he appeared quite easy, I merely ordered a dose of castor oil.

11 A.M. Child has had two severe convulsions in the last ten minutes, and is insensible, and the temperature has risen to 105½°. Repeated the cold bath, and reduced temperature to 98½°, when the child became quiet and slept. After this the temperature never rose above 101°, the bath was not repeated, and in a few days the child was well.

The coldness of the extremities and the weakness of the pulse in this case made me hesitate before resorting to the cold bath, but as death seemed imminent, and as the axillary temperature was so high, I concluded that any other means would fail, and that some risk was justifiable. It is remarkable that during the hour preceding the convulsions, the temperature rose from 103° to 105½°. I could cite a number of cases resembling the three here detailed, half of which would go to show the superiority of the treatment by cold baths over every other, when the temperature is high; and my friend and co-delegate here, Dr. Murphy, informs me that his experience with this plan of treatment entirely coincides with mine.

Where other indications for treatment exist, as malaria, teething, offensive accumulation in the alimentary canal, etc., it of course becomes necessary to attend to these also. In pursuing the plan I here recommend, I have always been guided by the thermometer, never resorting to the bath when the temperature has been below 100°, and always removing the patient from the water when the axillary temperature has fallen to nearly the normal standard of health.

It is much better to have the water tepid at first, on account of the excitement and alarm produced by sudden cold. I have not ventured to use the cold bath in convulsions complicating pneumonia, my experience being chiefly confined to those occurring in connection with dysentery, diarrhœa, cholera infantum, and malarious fevers. In these diseases, when the fever is high, although there be no convulsion, I have found no remedy that approaches the cold bath in its power of allaying nervous irritation and procuring quiet rest, and I am fully persuaded that all who resort to this mode of treatment once, will do so again.

Discussion on Dr. Holmes's Paper.

After the reading of the preceding paper, the President, Dr. Robert Barnes, of London, said:—Where there is an increased temperature in children, there is always some trouble with the blood, poisoning, or something else, which leads to convulsions. The question is, what develops convulsion? what is the first cause? It has been found that as the temperature rises, there is an increased liability to convulsions, and that as the temperature sinks, there is a decrease in this liability. Do we find that high temperatures always produce convulsions? In children, there is an exalted nervous irritabilty like that in pregnant women. Do they always have an increase of temperature? I have watched cases in which there has been no rise whatever—in uræmic convulsions after scarlet fever, for instance. In simple pyrexia I believe that cold water can be used to reduce the temperature; I have wiped the surface of the body with it, and found it to act well. The cold water acts by evaporation, and consequently reduces the temperature. The cold bath is a powerful remedy; its use by the Germans is a revival of a remedy first employed by Dr. Currie.

Dr. Thomas F. Rochester, of Buffalo, N. Y., said:—I have paid consider-

able attention to infantile disorders, and think I can corroborate the views advanced by Dr. Holmes in many respects. The subject is one which requires more attention than is paid to it. The reduction of the temperature by water, I regard as more safe than by the use of drugs. In my own city there have been many children lost, during the hot season, from what is called summer-complaint, which is ascribed wholly to the elevation of the temperature, but this I deem an error. The thermometer rises to 90° or 100°, the sky is blue and the sun bright, and yet the mortality is not as great as it is when the atmosphere cools off. Some years ago we had, in my city, a hot, dry spell, with but little sickness among the children; a hail storm came without any premonition, and at once infantile disorders set in. The diminution in the heat had caused the whole trouble. I have not examined the temperature before and after such atmospheric changes, but to me it seems conclusive that the fall in the temperature produces more diseases of children than the rise. I speak of convulsions as associated with the diseases of children, and make my remarks only in that connection.

Dr. Holmes, in reply, said:—I have lost a good many children from high temperature; and now think it well to reduce the frequency of the heart beats, for, as they become slower, the exhaustion lessens, and the beat becomes more forcible. My views are embodied in the short paper presented, and are based upon experience gleaned from my own practice.

OVARIOTOMY BY ENUCLEATION.

BY

JULIUS F. MINER, M.D.,

PROFESSOR OF SPECIAL AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

It is now about seven years since I announced to the profession that ovarian tumors could be removed by enucleation, and invited my professional friends to make trial of the proposed plan, describing, as well as I could, what I had done and the conclusions I had formed.[1] The idea that a tumor having such large arterial supply, could be removed without clamp, ligature, or cautery, though at first startling, received considerate attention, and, both in this country and in Europe, its successful results have led some of the most distinguished operators, not only to make trial of it, but to speak of it in high terms of commendation.

From the numerous reports and papers upon the subject, I discover that the exact manner of enucleation is not yet distinctly understood; some have spoken of a *clamp* after enucleation, others have spoken of cutting, the very thing that is to be avoided, while others still have limited the detachment of the pedicle to two or three inches above its base, thus showing me that I have never been fully understood as to the method of removing ovarian tumors by enucleation, a plan which, my experience convinces me, if properly understood and executed, possesses advantages over all others, and is of almost universal application.

It is well known that the ovarian tumor is surrounded by a peritoneal covering; that the pedicle, proper, usually divides into three or four parts, passing up over the walls of the tumor in bands of variable width, which contain vessels, often of large size, and which gradually diminish in thickness and in the size of the contained vessels, until finally they are lost in simple thickened portions of peritoneal covering. The peritoneal investment is not closely attached to the cyst, but separates readily, just as the peritoneum separates elsewhere in the pelvic cavity, being immediately lined by the subserous cellular tissue; thus no vessels of any considerable size enter the cyst. The tumor separates from its attachments with remarkable readiness, so much so that, in several instances, it is reported to have escaped the grasp of the operator and fallen spontaneously from the pedicle, accident thus plainly indicating the natural and proper method of removal.[2] The capillary vessels thus broken do not bleed, for the band contracts, and corrugates the larger trunks, while the broken-off capillaries ooze a little for only a minute or two, and a dry napkin, applied for a short time, is all that is required. The fear of hemorrhage is wholly unfounded, and I now say, without hesitation, that the danger of bleeding after this mode of proceeding is vastly less than the danger of slipping of clamp or ligature, in other methods in which

[1] Buffalo Medical and Surgical Journal, June, 1869.
[2] British Medical Journal, Nov. 26, 1870, p. 577; Braithwaite's Retrospect, July, 1871 p. 212.

the vessels are divided in their trunks. In this they are separated only in their extreme branches, and cannot give troublesome hemorrhage; it is seldom that any vessels are torn large enough to be seen as vessels or points of hemorrhage, and torsion is all that can be required in almost any case. If care is taken not to wound the vessels with either trocar, knife, or scissors, there will be no bleeding.

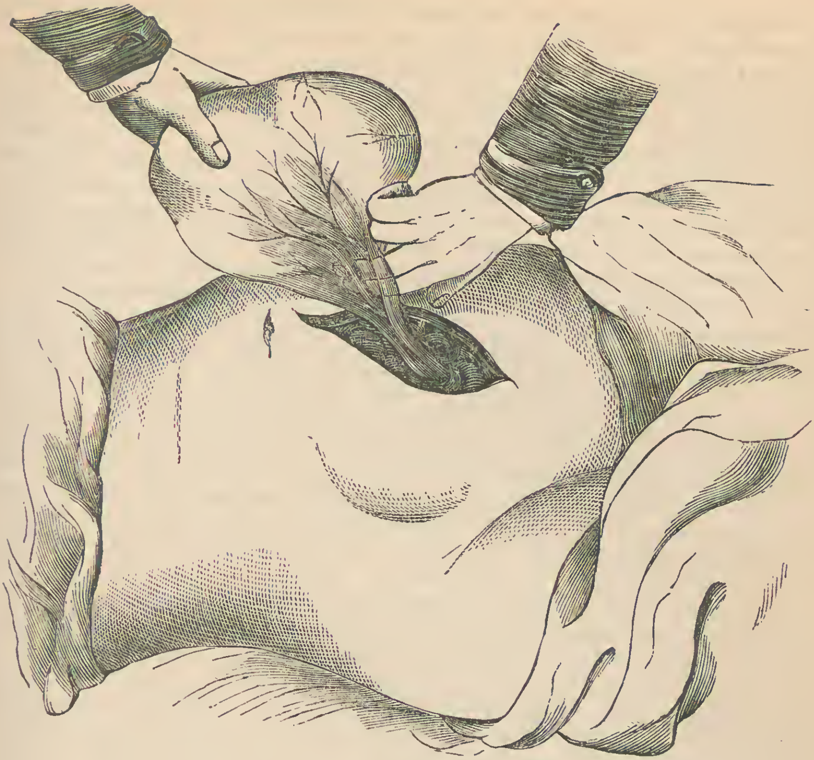
The tumor being removed, the operation is completed; there is no clamp to be used, for there is nothing to clamp; the pedicle requires no attention except to be carefully handled, and to be restored, as nearly as possible, to its original place; if the usual conditions are present, no drainage is necessary; and the incision may be closed as accurately as possible.

The bands referred to are to be grasped where they commence to diverge, raised from the cyst, and traced out to their terminations, often nearly around to the opposite side; the cyst is thus separated from its vascular supply, which is contained in these bands, other attachments being separated in the usual manner. Care must be taken not to wound or divide the vessels in their trunks, and, although the attachments will be found at points very strong, they can be forced off, or even with care a small piece of the cyst may be left attached to the pedicle, and no harm result, for it has a vascular supply, and is living tissue like the pedicle itself.

The method of enucleation has the further advantage that if upon trial it is for any reason thought impracticable, a clamp may be still applied, or the pedicle may be cauterized or tied with a ligature just as well as if enucleation had not been attempted. Few rules in surgery have no exceptions, and, though I believe that all ovarian tumors can be, and should be, removed by this simple method, supplemented when necessary by torsion or ligature to small vessels which bleed, still, to provide for all possible contingencies, I would assure the operator that a trial of enucleation is no hinderance to the subsequent adoption of any other plan that may be preferred, so that, while everything may thus be gained, nothing can be lost.

The accompanying cut, from a drawing by Dr. Edward N. Brush, who has several times assisted me in operating, will give a very fair idea of the procedure. The fingers of the operator are represented beneath a vascular portion of the pedicle, separating it from the walls of the tumor. This separation, as has before been observed, is to be carefully made, until the vessels are traced to their termination. To make the illustration plainer, the tumor is represented as raised from the abdominal cavity and supported by the hand of an assistant, but, of course, where extensive adhesions are present, this is impossible, and the risks of removal are greatly augmented. Formerly the operation in such cases was abandoned. When adhesions exist, they are to be separated, and the process continued to the pedicle.

There is no need to point out the advantages of this plan. Those who have studied the history of ovariotomy, and who are familiar with the difficulties and objections which may fairly be urged against the ordinary methods of procedure, will at once perceive that, if enucleation is successful, there is no pedicle to keep open the lower angle of the wound or to drag upon the parts—no unfavorable adhesions of the pedicle, no wires to be discharged by suppuration, and no crusts of burned tissue to be provided for. The abdominal cavity has simply been opened, and the diseased part removed; all that is left behind is capable of life.



It has been supposed that enucleation was designed exclusively for cases of extensive adhesion or short pedicle, in which no other plan could be adopted, thus lessening the number of incompleted operations. Certainly the method is adapted to such cases, but, instead of being reserved as a last resource, it should be chosen first, and the case regarded as most favorable in which it can be successfully accomplished. My surgical friends who have seen the operation, unite in regarding it as the most natural surgical procedure possible. To see it, is to be convinced of its entire feasibility and safety, while its advantages are too apparent to require a moment's consideration.

The following case first attracted my attention to this mode of treatment. I was invited to remove an immense tumor from the person of Mrs. Foster, of Cattaraugas County, N. Y. It was of many years' standing, and had been repeatedly tapped, but at length its contents became too thick to be drawn through the largest sized canula, and the patient's distress too great for endurance. The tumor was multilocular and very large, weighing, as nearly as could be ascertained, almost one hundred pounds. It was attached, throughout its entire circumference, to the omentum, intestines, walls of the abdomen, and all other parts with which it came in contact. These attachments were not so firm but that they could be broken up, and, with great care, the tumor was separated from the surrounding parts until the pedicle was reached. The process of enucleation had been carried on so extensively and successfully that encouragement was afforded for its continued trial; the pedicle was large, and extended over a wide surface, but by gentle and patient effort it was separated from its entire attachment to the tumor, and the immense growth removed without the use of a single ligature. The terminal branches of the vessels of

the pedicle gave out no more blood than issued from the vessels of the adhesions, and none of them required ligation. All hemorrhage soon ceased, and the incision was closed by the interrupted suture. The success of this procedure was complete, and the patient for nearly two weeks did not present a single untoward symptom, so that her recovery was considered almost certain. But she then began to lose her relish for food, grew weak and desponding, and died on the twentieth or twenty-first day after the operation. The fatal termination of this case detracts nothing from the success of this mode of treating the pedicle; indeed, so remarkable were the size and attachments of the tumor, that any attempt at recovery was surprising, and yet the feeble, emaciated, exhausted patient, continued to improve long enough to show that the manner of treating the pedicle was, at least in her case, unobjectionable.

On the fourth of June, 1873, I was called, in consultation with Dr. Mixer, of Buffalo, to see a patient, aged twenty-three, in whom he had diagnosed an ovarian tumor. After careful examination, Dr. Mixer's diagnosis was confirmed, and an operation was decided upon. The patient had suffered from pain in the right iliac region for about a year, but had menstruated quite regularly, though not to the usual amount, and had not noticed any enlargement of the abdomen until about six months previous to my seeing her, since which time the tumor had grown quite rapidly; she had never been tapped. On Monday, June 17, I operated, assisted by Drs. S. F. Mixer, C. C. Wyckoff and son, E. R. Barnes, and E. N. Brush. Dr. Mixer administered chloroform, which was afterwards replaced by ether. An incision about four inches in length was made in the abdominal wall, when the tumor was found adherent to the anterior surface of the abdominal cavity for a circumference of about nine inches. The attachments were carefully separated, but the walls of the tumor in this locality were so thin that it was accidentally ruptured, and some of its contained fluid escaped, whereupon a large trocar was immediately plunged in, and the contents of the cyst evacuated. The mass was now lifted from the abdominal cavity, and the pedicle brought into view. It was found to be of medium length, and its vessels were spread out over the tumor. I next introduced my finger beneath the central portion of the pedicle, at its least vascular part, between it and the sac, and by gentle manipulation separated it from the cyst. Two vessels only bled sufficiently to attract attention, and these were easily controlled by torsion. All further hemorrhage soon ceased on exposure of the part to the air, and, the cavity of the abdomen having been sponged out, the pedicle was returned without the application of a single ligature or other mechanical means to prevent bleeding. The slight oozing of blood caused by the separation of the adhesions from the abdominal wall ceased spontaneously. The wound was closed with the interrupted silver suture, supported by adhesive plaster, and warm flannel cloths were applied with bandages over the abdomen. The tumor was multilocular, and weighed eighteen pounds. On recovering from the anæsthesia, the patient complained of nausea, and vomited frequently. One-fourth of a grain of morphia was administered by hypodermic injection, and repeated once in four hours, and the patient was also given brandy and beef-tea. The following is a report of her condition as I found it on seeing her occasionally with Dr. Mixer. The temperature was not taken.

June 17, evening; pulse 120.

June 18, morning; pulse 108; vomiting at night.

June 19, morning; pulse 108; less vomiting.

June 20, morning; pulse 98; no vomiting; slept well; urinated without the use of the catheter; no swelling nor tympanites; wound was healing rapidly.

June 21; pulse 94; no symptoms of constitutional disturbance; slept and ate well.

June 24; pulse 84.

June 27; stitches removed; patient well.

During the whole course of recovery the patient declared that, with the ex-

ception of the nausea experienced during the first two or three days after the operation, she felt better than at any time just previous.

The pedicle in this case was of medium length, but too short to admit of its being brought out of the wound and secured by a clamp, without dragging upon the uterus, especially if any portion of it had been taken away with the tumor, as is the case when it is severed by the knife in the ordinary mode of performing ovariotomy. The vessels of the pedicle were large, and could be felt to pulsate plainly; and it is doubtful whether severing these with the cautery would have controlled the hemorrhage. Silk and metal ligatures have been employed successfully in many cases, and have been left in the cavity of the abdomen without producing any ill effects. Their employment, however, leaves within the peritoneum a foreign substance, which in most cases cannot but produce more or less inflammation, and any method which will allow the return of the pedicle to the abdomen, free from sources of irritation, must meet with approval. The question has been asked: "Can the pedicle be easily separated from the tumor?" In the case just narrated, the separation was accomplished with as great facility as attends the separation of cystic growths from surrounding parts in other portions of the body, and was easier, in fact, than was the detachment of the adhesions from the abdominal walls.

Prof. Logan, of the Medical Department of the University of Louisiana, in a private letter, speaking of an operation which he had performed for the removal of an ovarian tumor, the solid portion of which weighed sixteen and a half pounds, says:—"I was surprised at the facility with which the enucleation was effected; not a single vessel of sufficient size to throw a jet of blood presented itself, and no ligatures were, of course, required." In this case also, there was a rapid convalescence, with not a single bad symptom.

Upon these and similar facts is based the suggestion that the pedicle can, in ovariotomy, in some cases at least, be separated without ligature or cautery, thus avoiding many of its dangers. At first, this proposition may appear startling, and surgeons who have tied large vessels in the operation, or who have witnessed the fearful hemorrhage which sometimes takes place from the slipping of the clamp or ligatures, may regard it with some surprise, and may perhaps, without trial, look upon it as wholly impracticable; I should myself, probably, hold such an opinion, had I not had the opportunity of demonstrating to myself its entire feasibility.

An ovarian tumor is generally composed of a firm dense cyst, containing fluid of varied color and composition. It may, or may not, have a solid portion, but usually it does have more or less of a body, the remnant of an enlarged or degenerated gland. Upon the surface of this cyst is spread out the vascular, fibrous, cellular, and other tissues which compose the pedicle, but only the terminal branches of the vessels enter the cyst wall; the vessels may be quite large at their origin, but soon they are numerously divided, and enter the cyst, if at all, only when of capillary size. The attachment of the pedicle to the cyst is more easily broken than any one would imagine who had not tried the experiment in the manner described, and I am confident that the same efforts which are made to break up the adhesions to the peritoneum, omentum, and other parts, would, if extended to the pedicle, many times be equally successful.

If this method can be adopted without hemorrhage or other difficulty, its advantages are apparent. The pedicle can then be returned to the abdominal cavity without any of the objections which have been urged against this procedure. There is no ligature to be discharged by ulcerative process, or to become encysted, or to induce inflammation. There are no purulent or inflammatory products to be in any way removed or provided for; the pedicle is wholly living tissue, and has no irritative qualities which render its return to the abdominal cavity objectionable.

My object will have been wholly accomplished if the feasibility of enucleation in ovariotomy has been shown with sufficient clearness to insure a trial of the method by other surgeons.

Discussion on Dr. Miner's Paper.

After the reading of the preceding paper, the President, Dr. Robert Barnes, of London, said:—I am glad to hear the paper, as I was the first to introduce the method of enucleation into England. I think it a good method, but it cannot wholly supersede other modes of dealing with the pedicle. In some cases, enucleation is the only mode of removal practicable; but these are exceptions to the rule. I must say that I do not share Dr. Miner's dread of leaving silk and silver ligatures in the peritoneal cavity, for I have frequently seen them left there without mischief. I have also seen the perchloride of iron used to sponge bleeding points left after the sundering of strong adhesions, and without any of those formidable results which some writers attribute to its passage through the Fallopian tubes after intra-uterine injections. In ovariotomy, the great thing is security against hemorrhage; and that, I think, is best gained by the use of the clamp or the ligature. The operation of ovariotomy demands still more study than has been given to it, and I congratulate Dr. Miner upon having very materially added to the stock of knowledge regarding it.

Dr. James P. White, of Buffalo, said:—I am cognizant of twenty or thirty cases in which enucleation has been used. It is not a very difficult operation, but in some cases it is impossible—for instance, where the growth of the tumor has been rapid and the pedicle is short and large. In these cases, the cyst cannot be safely enucleated. I have no doubt, however, that enucleation is often the best method of treating ovarian tumors, but the subject merits a great deal of study and consideration, and the cautery, the clamp, the ligature, and enucleation, all deserve attention, and should be severally used according to the special indications of individual cases.

Dr. E. R. Peaslee, of New York, said:—We should not confine ourselves to any one method of treatment in the removal of ovarian cysts. Nor is enucleation always feasible. In some cases, short and large vessels enter into the cyst directly from the pelvis, and do not become capillary. In these, enucleation will not answer, because it cannot arrest the hemorrhage. Such an instance I have met with, and the patient bled to death. Again, owing to the thinness and the friability of the cyst-wall, it will sometimes break down before the adhesions can be broken up. But I feel under great obligations to Dr. Miner for introducing this method, for I have removed tumors by enucletion, which I am confident could have been removed in no other way. In most cases the ligature can be used, and I then see no particular advantage to be gained by enucleation. But I would adopt it in cases of cysts adherent to the liver. I am myself inclined to the use of the ligature, which I generally cut close. As I have only once seen the pedicle slough, I do not share Dr. Miner's fears on that score.

Dr. G. Kimball, of Lowell, Mass., said:—I have tried enucleation but once, but believe that I might have saved some lives had I known of this method

earlier in my practice. I feel very much indebted to Dr. Miner for his suggestions on this subject. Dr. Keith's great success has been obtained with the cautery, and I think that the profession is still at sea as to the proper method of dealing with the pedicle. I myself generally use the clamp, but I adapt the treatment to the particular case.

Dr. White said:—As a rule, I prefer cauterization, because it leaves fewer foreign bodies in the cavity of the abdomen; and I am sure that, in my practice, I have seen as many children born from women who have lost one ovary as I have lost cases of ovariotomy. I think that the treatment of these tumors should be eclectic, and that each case should be separately studied with a view to its treatment.

Dr. Alexander R. Simpson, of Edinburgh, said:—In regard to the application of the cautery, Dr. Keith has used it very successfully; personally, I am ready to use any method that the case may demand. The great strength of Dr. Keith lies in the thorough preparation of his cases, and in the care which he takes with them. There is always a difference in operators, and Dr. Keith does not consider minutes wasted that will prevent hemorrhage into the peritoneal cavity.

Dr. Theophilus Parvin, of Indianapolis, said:—Enucleation is of use when the pedicle is too short for the clamp. I have had two cases: one complicated with pregnancy was attended by considerable hemorrhage. This I checked by the application of flannels dipped in hot water. In such cases I can recommend hot water, and I referred to the same agent in the discussion of yesterday on uterine hemorrhage. I think, contrary to Dr. Miner's statement, that it is settled that there is no peritoneal coat to an ovarian tumor, as there is no peritoneal covering to the ovary itself. Enucleation is of value where there are peritoneal adhesions, but I believe that it can be very often dispensed with by the use of hot water. I recognize its advantages, but do not think that it is the only treatment for ovarian tumors.

Dr. Miner, in reply, said:—I agree that possibly in some cases enucleation may not be of service, and that torsion, the ligature, and even the cautery may have to be used. But in ordinary cases of ovarian tumor, I deem it to be a plain piece of surgery; and I have myself never seen a case in which the cyst could not have been removed by enucleation. Where there is bleeding, I resort to torsion; but enucleation does not interdict the subsequent use of the clamp, the ligature, or the hot iron.

THE TREATMENT OF FIBROID TUMORS OF THE UTERUS.

BY

WASHINGTON L. ATLEE, M.D.,

OF PHILADELPHIA.

In opening the discussion on The Treatment of Fibroid Tumors of the Uterus, a question that has for many years engaged my attention, it will be imposssible to present the subject properly in the short space of time allotted to me; and I must, therefore, ask your indulgence if, in adhering closely to the text and compressing my material, I should fail in satisfactorily elucidating the several points in this paper.

I beg, also, to premise that, in bringing this subject before the Section on Obstetrics, I shall not go into the detail of every method of treatment. This I think would be out of place before an assembly of such enlightened men, who are already familiar with its written history. I shall merely refer to my own experience. Every gentleman, who will engage in this discussion, has an experience of his own, and if each one will bring his personal contributions, able architects of our profession will rear a structure out of these materials which no individual could erect from his own observations, and which will stand as a lasting memorial of this day's work. In this way we will be likely to arrive at the best practical results for the benefit of Science, Art, and Humanity.

My methods of treatment have been surgical and medicinal. In the use of medicine I have principally confined myself to iodine, ergot, and muriate of ammonia. Many years ago I lost faith in iodine, and now seldom use it, and only as a local application. As early as 1845, I introduced the use of ergot in the treatment of uterine fibroids, and have ever since employed it. In proof of this I may refer to my essay on Fibrous Tumors of the Uterus, published in the Transactions of the American Medical Association for the year 1853. Ergot, no doubt, acts in two ways in influencing the nutrition of fibroids of the uterus: (1) on the muscular tissue of that organ, and (2) on the capillary circulation of the tumor itself by contracting its smaller vessels. Notwithstanding this action of the medicine, I have never been so fortunate as to see a fibroid quietly disappear under its sole influence, although in many cases the size has been diminished, while in others no effect has been produced. The reason of its variability in action may be explained in the course of this paper. Recently, Hildebrandt has introduced the hypodermic use of ergot, and with results, in his hands, quite extraordinary. I cannot, however, conceive how this agent can accomplish more by its subcutaneous employment than by its administration by the natural passages. It certainly acts more promptly through the cellular tissue. But it is questionable whether this increased speed of action is a sufficient compensation for certain inconveniences to the patient from this mode of its application, as well as for the greater tax on the time, convenience, and patience of the medical attendant.

In the consideration of the treatment of uterine fibroids, it must also be kept in mind that spontaneous cures may result in consequence of

fatty degeneration; that diminution in the size of the tumors is often observed in advancing age, through senile atrophy of the muscular fibres; that fibrous induration sometimes occurs, the muscular tissue becoming scarcer as the connective tissue hardens, and that this induration is followed by calcification and an arrest of growth.

With these preliminary remarks, I will proceed to discuss the subject of treatment more definitely. In doing so understandingly, it will be necessary to keep in view the relative position of the tumor with the uterus. Hence I will make the somewhat arbitrary division into the following heads:—

I. Tumors usually accompanied with hemorrrhage, embracing (1) fibroids occupying the vaginal canal; (2) fibroids within the cavity of the uterus; (3) interstitial, submucous fibroids; (4) interstitial fibroids proper; (5) recurrent fibroids.

II. Tumors usually not accompanied with hemorrhage, including (1) interstitial, subperitoneal fibroids; (2) sessile, peritoneal fibroids; (3) pedunculated, peritoneal fibroids; (4) interstitial, cervical fibroids; (5) myomatous degeneration of the uterus; (6) fibro-cysts of the uterus.

I. Tumors usually accompanied with Hemorrhage.

(1) *Fibroids expelled from the Cavity of the Uterus, or occupying the Vaginal Canal.*—The treatment of these tumors will vary according to their size. When small, with a slender pedicle, the tumor may be grasped as high as possible on its neck by means of Luer's polypus forceps, or a similar instrument, and twisted off, or, in other words, removed by torsion.

When larger, with a pedicle not thicker than a finger, it may be seized and brought down with some force so as to stretch the pedicle, which may then be severed at as high a point as possible with Cooper's hernia bistoury, or a probe-pointed bistoury properly wrapped and protected.

When quite large, distending the vagina or filling up the pelvis like the head of a child, a small obstetric forceps may be applied to it, and then placing the patient under the influence of an anæsthetic, with the assistance of supra-pubic pressure, the tumor may be gradually brought through the os externum. Having accomplished this, one of several plans may be adopted for the purpose of detaching it: (*a*) By means of the bistoury the proper coat of the tumor may be severed all around, about an inch or so beyond the insertion of the pedicle, and then the upper end of the tumor enucleated from its peduncular attachment; (*b*) the substance of the pedicle may be directly severed by the knife; (*c*) the pedicle may be divided by the *écraseur*. I have used all these methods, and it is best to be prepared for either operation, as the surgeon must be governed by the circumstances of each case. When it can be accomplished, I prefer the first method, or that by enucleation of the pedunculated end of the tumor.

Immediately after the removal of these large tumors we should use a tampon, charged with persulphate of iron or other efficient hæmostatic and antiseptic, adapting it well against the amputated stump, and allowing it to remain from twenty-four to forty-eight hours. The raw and, usually, inflamed surfaces should afterwards be treated through the

speculum by suitable applications until they are brought into a normal condition.

It may be noticed that I have not referred to the ligature as one of the methods. I have long since abandoned this plan, preferring immediate ablation of the tumor.

(2) *Fibroids entirely within the Cavity of the Uterus.*—The treatment of fibroids inclosed within the cavity of the uterus must depend somewhat on their size and locality. When large and of long duration, having distended the body of the uterus and dilated the cervix as does the head of a child in the last months of gestation, an examination by the finger will discover a mere uterine ring, through which by firm pressure, particularly when counteracted by supra-pubic support, a tumor within may be detected. This no doubt is the condition precedent to the first form of fibroid which we have considered, and the lapse of time in all probability, if the patient should hold out, would accomplish the same state of things. It is, however, not always safe to wait, but safer to facilitate measures by imitating the processes of nature. To make the tumor more accessible, the os uteri should be dilated by the usual means, and at the same time ergot administered to excite and maintain the contraction of the expulsive fibres of the organ, and in this way also aid in opening the uterus. Or, instead of using dilators to open the os uteri, the action of ergot may first be established, and afterwards the tense edges of the os may be nicked with a bistoury, thus successively dividing the circular fibres, and accomplishing the object in much less time. As soon as the mouth of the womb is sufficiently expanded, a small obstetric forceps may be introduced and applied to the tumor in the same way as it is to the head of a child. Traction should now be made on the tumor under the influence of an anæsthetic, and if the circular fibres, as will probably be the case, should resist its escape, the bistoury must be employed until all resistance is overcome, and the tumor is brought into the cavity of the vagina. It is now in the position described under the first head of our subject, and may be managed accordingly.

There is, however, a very important difference between a tumor passing from the uterus into the vagina spontaneously and one brought there by violence, and that difference involves a very grave practical point. This will be at once apparent when it is stated that in the former case the tumor alone occupies the vagina, and that in the latter it is very apt to be accompanied by an inverted uterus. This is particularly liable to occur when the pedicle is attached to the fundus. Usually too, in vaginal fibroids, we find a moulded and elongated pedicle which is readily and safely managed, but in the tumors under consideration the pedicle is usually sessile, and affords but small space for any surgical appliance. Hence, the inverted fundus uteri is in great danger of injury and mutilation, and unusual care is required in amputating the tumor. I believe the safest mode is to enucleate the upper portion of the tumor from its proper coat, and thus free it from its uterine connections. Of course, after this is done, the inverted uterus should be at once replaced after proper styptics have been applied to the raw surface, and the case treated upon general principles.

These fibroids, however, are not always as simple and as easily managed as has been just described. From some cause or other the tumor may have formed adhesions to the surface of the uterus, independent of its original, peduncular attachment. These adhesions may be so situated as to interfere materially with the dilatation of the os uteri, or with the

introduction and application of the forceps. It is necessary, under these circumstances, as soon as they are recognized by the finger, to sever them with the bistoury until the surface of the tumor is free. If, in consequence of such adhesions, or of a lateral origin of the pedicle, the ordinary forceps cannot be applied, Museux's forceps, or appropriate hooks, may be substituted to seize and bring down the tumor after the os uteri is sufficiently dilated.

Besides the fibroids referred to, there are other tumors in the cavity of the uterus which are entirely concealed, and, either from their diminutive size or a very adipose abdomen, cannot be detected. The cervix uteri may be intact, and there may be no bulging of the uterine wall recognizable by the finger in the vagina. Yet the symptoms may be so diagnostic of their presence that we are bound to be governed by them alone. In such cases we must dilate the cervical canal by sea-tangle, sponge tents, etc., until we are able to pass the index-finger and explore the interior of the uterus, and get access to the tumor. The dilatation must now be carried further, so as to admit, in addition to the finger, the necessary instruments for the removal of the growth. These are usually a strong, slender forceps, or hook, and a long-handled, probe-pointed bistoury, or a probe-pointed, semicircular knife. A small wire *écraseur*, passed above the forceps, will answer the same purpose. If the tumor have a small pedicle, it may be removed by torsion.

(3) *Interstitial Submucous Fibroids.*—These are tumors which, originating in the wall of the uterus, develop mainly towards the mucous surface. Like the two preceding forms, they more urgently demand the surgeon's attention in consequence of inducing uterine hemorrhage. When the cervix is not implicated in this class of tumors, and the body of the uterus alone is involved, it is best not to be too precipitate in resorting to surgical means for relief. As long as hemorrhage can be controlled, and blood saved to the patient, it is best to depend upon the judicious employment of ergot and other remedies, rather than to resort to a hazardous use of the knife. A tumor thus situated, with muscular walls on one side of it and a mere mucous covering on the other, will be in a favorable condition for ergot to gradually expel it from its muscular bed, and force it into the uterine cavity, and, in proportion as this is accomplished, we secure the aid of all the longitudinal fibres of the uterine walls in propelling the growth against the circular fibres of the cervix, and in causing a gradual opening of the os uteri—thus finally reducing this form of tumor to the second variety before considered.

If, however, exhausting hemorrhages cannot be controlled, and fatal consequences threaten, other and more decided measures must be adopted. The os and cervix should be well dilated, so as to get free access to the interior of the uterus, and to be able to command the surface of the tumor. As soon as this is done, efficient doses of ergot must be administered, and, when its action is established, a long, probe-pointed bistoury, guided by the index finger of the left hand, should be passed up flatwise into the uterus, as in using a sound, and carried over the face of the tumor until it reaches its upper border. An assistant should now grasp the lower part of the abdomen and steady the uterus. The bistoury is then turned with its edge against the tumor, and boldly pressed into it and drawn downwards through its dense tissue, so as to slit open both its mucous covering and its proper coat, burying the knife well in the fibrous mass, and carrying it downwards until it makes its exit at the lower border of the tumor. As the knife passes through the dense tissue,

a decided grating is perceptible. It is a remarkable and interesting fact that, if hemorrhage have existed before this incision, it will cease after it has been made, and it will sometimes be found that when nothing else will arrest hemorrhage, a free use of the knife will accomplish it. Immediately after the section, an attempt should be made to enucleate the tumor from its bed, which can often be accomplished if the tumor be not too massive. Should it not be removed at once, it is apt soon to become disorganized and dead, throwing off a very offensive, dirty, watery discharge, and endangering septicæmia. Ergot must be continued, to maintain the contraction of the uterine tissue, antiseptics administered by mouth, lungs, and vagina, and the patient sustained until the tumor is removed by the surgeon, or is discharged in a softened mass resembling wet tow. The danger to be apprehended after this operation is blood-poisoning from dead matter. This is very much diminished when the tumor is removed by one operation, but, even then, the extent of raw surface remaining after the tumor is taken away, sometimes causes toxæmic symptoms.

(4) *Interstitial Fibroids Proper.*—These are tumors which originate deeply in the substance of the uterine wall, and during their growth and development are surrounded by a pretty uniform coat of uterine or muscular tissue, neither impinging on the mucous lining on the one side nor on the peritoneal covering of the organ on the other. As a general rule, the demand for active treatment in these cases is not as great as in the submucous varieties. These intra-mural tumors, however, are the very ones most amenable to the mode of treatment that has recently claimed the attention of the profession, viz., the hypodermic use of ergot. I can understand how the tonic contraction induced by ergot can impede nutrition in a tumor so located, but I cannot conceive how absorption could be promoted under a similar amount of compression obstructing the absorbent vessels. In the treatment of interstitial fibroids I think it best to use ergot periodically and not constantly; employing it in anticipation of and during the menstrual periods, and associating with it the continuous use of an alterative sorbefacient, such as muriate of ammonia. If ergot acts mechanically in destroying the life of a tumor, then, when that is accomplished, the stress or pressure should be removed, so that this dead matter may be absorbed. As long as this dead material is hermetically encased in living tissue, unaffected by atmospheric influences, it is not likely to become offensive or toxic, and may be carried off by the absorbents like other molecules of dead matter in the regular processes of repair, without infecting the general system. As there is a tendency for fibroids to increase in size before each menstrual period, in consequence of the greater determination of blood to the organs of generation, so there is a diminution in their size after menstruation subsides. Hence ergot is calculated to act beneficially, when given in time, in arresting this supply of blood to the tumor; and yet we must not always attribute the diminution in size, which usually follows menstruation, to the influence of ergot, as it is a natural physiological sequence.

These interstitial fibroids often assume a great size, and in doing so stretch the cavity of the uterus to an unusual length, increase the vascularity of the organ and the size of the vessels pervading the corresponding mucous covering, and, during the menstrual period, these unsupported vessels are rendered turgid and congested, and, giving way, produce copious and dangerous hemorrhages. When this is the case, and danger cannot be averted by medication, surgical means are demanded. A bold, free inci-

sion through the muco-muscular envelope of the tumor, and through its proper coat, burying the knife into the fibroid substance, will be attended by an arrest of the bleeding. This may be followed by an enucleation of the tumor—the several steps of the subsequent operation being the same as detailed under the head of Interstitial Submucous Fibroids.

Sometimes the interstitial fibroid, even when very small, may produce the most violent symptoms, both local and reflex, leading even to death; and may be so situated that, under certain circumstances, its existence may not be suspected, and that, even if correctly diagnosticated, it could not be removed by any ordinary operation. This is particularly the case when the tumor originates in the lateral part of the fundus uteri and becomes intra-ligamentous. Such cases, fortunately, are extremely rare, and I will endeavor to illustrate them by the detail of one which recently proved fatal:—

Mrs. D. G. S., aged 34 years, was brought from the interior of the State to Philadelphia, and placed under my care. She was small in stature, but excessively corpulent, particularly in the abdominal wall. For a long time she had suffered the greatest agony and distress, and had had frequent and most violent convulsions. All the symptoms were distinctly traceable to the uterus. There was decided endo-metritis, and the slightest touch of the sound would cause terrific spasms. There was also extreme tenderness confined to a small spot in the hypogastric region, on the right of the linea alba, so that she could not tolerate the most gentle pressure. The treatment during the winter of 1874–75 relieved the endo-metritis and several of the reflex symptoms, and, although she had not fully convalesced, she went home with the expectation of gradually regaining her health. But she again became worse, and her husband, an intelligent physician, conducted the treatment, but without controlling the symptoms. I visited her several times during the winter of 1875–76, and I never saw a greater sufferer. The spot in the hypogastrium was the point of trouble. She had not been able to lie down for months, and the right thigh was kept flexed all the time. Her suffering was so constant and intense that both she and her husband begged me to open her and remove the womb. She required the constant use of the most powerful anodynes to afford the least comfort. Finally symptoms of cerebral congestion supervened, and in a few days after, on the twenty-third of March last, death came to her relief. In exposing the abdominal cavity after death, about four inches in thickness of adipose tissue had to be penetrated. The uterus was enlarged and highly congested. Its cavity was three and a half inches long. The lining membrane was normal. In the right wall of the fundus was an interstitial fibroid, not over two inches in diameter, surrounded by a dense wall of uterine tissue, and so closely adherent to its capsule that it could not be shelled out or enucleated. The capsule had evidently been in a state of inflammation, and this was thought to be the cause of the intense and fatal suffering. Both openings of the Fallopian tubes were obliterated.

In reference to this interesting case I wish to state that I had appointed the very day on which I witnessed the post-mortem examination to visit the patient to decide upon the feasibility of extirpating the uterus. In consequence of the extreme amount of abdominal fat, as shown by the examination, this would have been very difficult, if not impracticable. For the same reason it was impossible to make a correct diagnosis of the case, and the fibroid discovered after death was not at all suspected to exist before. Of course the case might possibly have been made out by the barbarous practice of exploring with the hand through the rectum. If such an extreme case were again to present itself to me,

particularly in a thin patient, I should think it my duty to remove the diseased organ.

(5) *Recurrent Fibroids.*—The recurrent fibroid is polypoidal in character, and is supposed to be reproduced, after its removal, from the same pedicle. These cases are very troublesome, because, after one tumor is removed, there may be repeated recurrences of others, resembling in this respect, and in this only, the several forms of malignant disease. The operation for their removal is the same as for that of the ordinary uterine polypus, but, as this is a much more grave trouble, I wish to submit to the Section a proposition embracing more extensive surgical interference. This proposition is based upon the treatment of two cases of very great interest, which I beg permission to relate.

In the first case I removed eleven successive tumors, after which the patient recovered and had no return.

On December 27, 1860, I visited Mrs. T. W. S., aged 31 years. Menstruation for the first four years was small in quantity and free from pain, but afterwards was accompanied with extreme agony during the first day. She married at the age of 24 years, in one year after gave birth to a child, and had a miscarriage afterwards. The menses were regular, having only missed the last period. In April, 1858, she first discovered something wrong in not being able to pass water. A large quantity was drawn away by the catheter, which operation had to be repeated. Several physicians saw her, and diagnosticated malposition of the womb, and very violent efforts were made to restore it to its normal position, but without effect. June, 1860, she had a sudden attack of severe pain, which so entirely disabled her that she could not walk for several weeks, suffering much of the time with the most dreadful bearing-down pains. After a period of intermission the expulsive pains again returned with extreme violence, and, on November 28, 1860, while using the catheter, she felt a tumor in the vagina which she supposed to be the womb. The pain now diminished, but the size of the tumor gradually increased, and it finally protruded through the os externum. During the above period she had copious discharges from the vagina of bloody clots and a greenish, slimy, and offensive fluid, changing usually about twenty-five napkins in a day.

When I saw the patient she was perfectly blanched and anæmic, with a small thread-like pulse, and evidently in a state of toxicohæmia. A tumor, as large as a small adult head, protruded from the vagina, and was lying between the thighs. It was in a gangrenous condition, and gave off a most offensive odor. The index finger, passed into the vagina in front, came against the anterior lip of the os uteri about two inches up. It was stretched across the front face of the tumor, which was continued into the uterus as far as the finger could reach. The sound struck the fundus uteri one inch above the anterior lip. The vagina behind the tumor was also explored. A *cul-de-sac* was reached at the distance of one and a half or two inches, formed apparently by the inverted vagina coalescing with the tumor. The growth had clearly been developed in the posterior wall, and had been extruded by the uterine efforts from the cavity of the organ. The circulation was still maintained in the posterior portion of the mass. The pedicle was about two inches thick. With the assistance of Drs. Drysdale and Burpee, I removed the mass by means of the *écraseur*. Although much decomposed, its weight was one and a quarter pounds. For several weeks the patient continued to be very ill with septicæmic fever, but finally fully recovered.

April 17, 1862, the patient consulted me again, stating that she had remained well until three months before, when she had had a copious puruloid discharge, and that one week before seeing me another tumor had begun to protrude. On examination, I found that the relative positions of the tumor and uterus were now different. The former, instead of being behind the os tincæ, was anterior to it, and the expanded posterior lip could be distinguished in the hollow of the

sacrum. This second tumor increased to a considerable size, and was removed in the same way. At the same time a hard tumor was felt occupying the hypogastric region. A few weeks after the removal of the second tumor it was followed by a third, which was also taken away. A mass still occupied the hypogastric region.

The following December she was taken with excessive hemorrhage, requiring the use of the tampon. Subsequently quite a large tumor was expelled from the vagina, and at the same time the supra-pubic tumor disappeared. This, the fourth tumor, was removed by the *écraseur* on the 9th of January, 1863, and the operation was followed by a rapid recovery. June 1, 1863, another large tumor, the fifth, was removed in the same way. January 21, 1864, the sixth tumor, less in size, was removed. I could plainly trace this one into the cavity of the uterus, and the anterior lip of the os stretched over it, the sound entering anterior to the mass two and a half inches. At the same time I recognized a hard tumor in the right inguinal region. August 24, the same year, the seventh tumor was removed. The eighth, ninth, and tenth were subsequently removed up to the 20th of May, 1866. The eleventh tumor was taken away on the 18th of August, 1867, with the assistance of Dr. J. Nicolaysen, of Christiania, Norway, now Professor of Surgery in the University of Norway. After this no tumor could be detected anywhere.

After the eleventh operation there was no return, and the patient regained her health, at least for two or three years, after which I lost sight of her.

In reviewing the above case—its extraordinary features, its long duration, its imminent perils, and its almost endless recurrence—the question has often presented itself to me: Would not extirpation of the uterus at an early period have been not only justifiable but preferable?

A question also of great interest—the pathology of the so-called Recurrent Fibroids—might be discussed with profit, but this is not compatible with our present subject. Both questions will be in a measure involved in the detail of another case, which I think would have exhibited the same features as that above narrated, but which was terminated quickly and happily by a different mode of treatment:—

On May 15, 1874, Mrs. C. T. was brought from the interior of Pennsylvania for treatment. She was 30 years of age, had first menstruated at the age of 14 years, and had continued to be regular until her marriage in 1870. Two years before marriage she began to suffer from a burning sensation in the pelvic region, and from bearing-down pains, which gradually grew worse. Soon after marriage menstruation became more copious, and, eighteen months after, she was seized with great pain, accompanied with excessive flooding. Subsequently she was confined almost constantly to bed by copious hemorrhage, intense suffering, and constant nausea and vomiting. She had never conceived. Prostration, emaciation, and anæmia were very strongly marked.

The uterus was enlarged to the size of a four-months' pregnancy, the cervix fully expanded, and the os, round and ring-like, merely admitted the point of the index finger. A hard, smooth tumor could be felt within. I immediately put her on the use of iron and ergot, but, notwithstanding, she had an overwhelming attack of flooding and pain. By the 22d of June the condition of the patient and of the os uteri was such as to warrant me to proceed with an operation. Assisted by my son, Dr. W. Lemuel Atlee, I introduced a forceps into the cavity of the uterus, and, grasping the tumor, made traction while the patient was under the influence of an anæsthetic. As the os was not sufficiently open to allow the tumor to escape, it was nicked by the bistoury as it tightened over the descending mass, which finally was delivered into the vagina with a sudden slip, and afterwards through the os externum. The *écraseur* was now applied, but, proving to be faulty, was removed, and the pedicle was severed by the bistoury. While preparing for this part of the

operation, I was struck with what appeared to be an unusual elongation of the pedicle, which was dotted over with several molluscum-like bodies. Apprehending that this might be the uterus itself inverted, I was careful to make the section close to the tumor. Immediately afterwards I tamponed the vagina with strips of muslin wet with Monsel's solution of iron.

The operation was followed by intense pain, and in the course of two or three hours by hemorrhage, which was controlled by removing the first tampon and substituting small sponges. There were also incessant sickness and vomiting, which, the patient said, always followed the loss of blood or the use of anæsthetics. These symptoms were subdued by opiates in the course of twenty-four hours. The pulse increased in frequency, and the case looked rather alarming. Next day the sponges were removed, an examination was made, and a rough, irregular, tumor-like mass still occupied the vagina. I could not divest myself of the apprehension of its being an inverted uterus. The parts were so very tender that a satisfactory examination could not be made. This soreness continued for eight or ten days.

The regular menstrual period came on the first week in July, accompanied with very little pain and a moderate discharge. On the 13th I repeated the examination, and found the same state of things. The os grasped the tumor, and a sound passed up entered the uterine cavity the normal distance of two and a half inches. From this examination I inferred that there was no inversion, and that there still remained a portion of the original tumor. Pressure over the pubes did not enlighten me. Perhaps a finger in the rectum would have disclosed the true state of the case. I seized the body with a strong double tenaculum, brought it partially through the os externum, applied the *écraseur*, and on working the instrument found the tissue unusually resisting, requiring much force and time in getting through it, and indeed having to finish the operation with the knife. On examining the mass, after its removal, I was surprised to find it to be the body of the uterus.

[The specimen was then exhibited. The mucous surface was dotted over with several small tumors in different stages of development.]

Great pain and sickness of the stomach succeeded the operation as before, but did not last so long. Much less bleeding accompanied the amputation, and none followed it. The patient had a rapid and excellent recovery, grew fat and hearty, and, with the exception of slight coccyodynia, has been in the continued enjoyment of perfect health. Menstruation has not occurred since. The speculum reveals a perfect os tincæ, and the sound enters only one inch.

Although the treatment of the above case was ultimately conducted on an error of diagnosis, does it not teach a valuable practical lesson? If the history detailed to you this day explains and illustrates the pathology of the so-called recurrent fibroid of the uterus, and if each abnormal body on the surface of the womb is liable to be successively developed into a life-endangering tumor, will not the amputation of the body or the entire removal of such a diseased organ be the best mode of treatment, keeping in view the comfort and life of the patient?

II. Tumors usually not accompanied with Hemorrhage.

(1) *Interstitial Subperitoneal Fibroids.*—These are tumors having the same relation to the serous coat of the uterus as the interstitial submucous fibroids have to the mucous coat. They are imbedded in uterine tissue except where they present towards the abdominal cavity, and there they are covered only by peritoneum. Their locality renders them much less serious in their consequences to the patient, and does not call so

imperatively on the surgeon for interference. Still, circumstances might arise in which relief would be demanded. Treatment in these cases will accomplish a great deal, either with or without reference to an ultimate surgical operation. I have just hinted at the action of ergot in the submucous fibroids. It is the same, in an opposite direction, in the subperitoneal tumor. The tendency of any foreign body, when acted upon by the contractile efforts of uterine tissue, will be towards the point of least resistance. Hence ergot, acting forcibly on the muscular substance of the uterus, in which the fibroid is deposited as in a closely-fitting nest covered merely by a delicate serous membrane, must, as a necessary result, gradually diminish the bed of the tumor, and as gradually cause the mass to encroach upon the abdominal cavity. I have no doubt that nature herself sometimes converts this kind of tumor into a sessile or even pedunculated fibroid. And hence, by following her teachings, by means of ergot we are able greatly to aid her in accomplishing such results. Supposing, however, that this result has been reached, the tumor has not been destroyed nor diminished, but only changed in its locality, for I very much doubt whether ergot has influenced its growth in this situation. Still, our patient has been benefited by relieving a very sensitive and irritable organ of a troublesome tenant, and by placing the tumor in a position more accessible to the resources of surgery if the case should ever demand it.

In interstitial subperitoneal fibroids, it would be extremely hazardous to invade them by the knife from the interior of the uterus, and in this way attempt their enucleation or even disorganization and devitalization, as their thin serous coating would not be a sufficient barrier to protect the abdominal cavity from being entered, which would necessarily cause fatal results. It would be much safer, after the administration of ergot, to open the cavity of the abdomen, expose the surface of the tumor, divide its peritoneal coat with the knife, and enucleate the mass from its muscular bed. Should bleeding occur, the vessels could readily be secured as they are in ovariotomy, and to guard against oozing and accumulations in the abdominal cavity a siphon-drain could be carefully placed and brought out of the lower angle of the wound. At the same time, if deemed necessary, a communication between the bed of the tumor and the cavity of the uterus could be made, and thence through the cervical canal with the vagina, and a siphon introduced so as to assist in carrying off fluids also in that direction. These precautions would go very far in preventing septicæmia and fatal inflammation.

(2) *Sessile Peritoneal Fibroids.*—These are tumors which present bodily into the abdominal cavity, but are closely seated on the exterior surface of the uterus, and have a broad base. They do not sink deeply into the uterine tissue itself, and do not elongate the uterine cavity. They may be removed in the same way as the subperitoneal variety, but the same precautions need not be exercised with regard to the uterine bed which receives the tumor. Indeed, in both varieties, a peculiarly formed tube of silver, glass, or hard rubber, around which the detached coats of the tumor could be fastened or ligated, might be secured with one end in the bed of the tumor, while the other could be carried out of the lower end of the abdominal wound, thus acting as a siphon in drawing off the fluids, or as a conductor for the introduction of antiseptic washes from without. By the time the ligatures should have become loosened, the drainage tube could be removed, and a fistulous track would remain to fill up and heal by granulation and cicatrization.

In cases of ovariotomy, when complicated with small sessile fibroids, I have not hesitated to enucleate them before closing the incision, being careful, if there were any oozing, to carry a tent from the raw surface to the lower angle of the wound.

(3) *Pedunculated Peritoneal Fibroids.*—These are fibroids having a distinct pedicle, either membranous or myomatous, attached to the exterior surface of the uterus, and contained within the cavity of the abdomen. These tumors, being beyond the limits of uterine action, are not usually influenced by the use of ergot, but do sometimes yield to the sorbefacient action of muriate of ammonia uninterruptedly maintained for a long time. If they fail to yield to medical treatment, and induce such severe symptoms as to destroy personal comfort or jeopard life, they may be removed, as are ovarian tumors, by abdominal section, and the pedicle secured by the clamp or ligature. The operation need not be described. I may, however, remark that, in proportion to the size of the tumor, the incision through the walls of the abdomen must necessarily be larger than that required by ovariotomy, and that the pedicle will need more careful attention. Should the pedicle be short, we can add to its length by incising the proper coat of the tumor around its base, two or three inches beyond the stem, and shelling it off and making it part of the pedicle. I have several times removed these tumors in this way.

(4) *Interstitial Cervical Fibroids.*—These tumors occupy the vagina, but are not ejected from the cavity of the uterus, and consequently are not pedunculated, and are not capable of being treated in the same way as uterine polypi. They are surrounded by the tissue of the cervix, and are imbedded within it. When small, resembling a bullet submerged in the cervical structure, a simple incision carried through the tumor, so as to bisect it, will often be sufficient to lead to its decay and destruction. To make its disorganization more certain, the surfaces of the cut fibroid may be touched through the speculum with a pencil of vegetable caustic or of *potassa-cum-calce;* or, better, the small mass may be entirely enucleated by the point of the finger after opening its capsule. When the tumor is large, swelling out a portion of the cervix to the size of a walnut or an orange, it will be necessary to make a free slit in its envelope and enucleate the mass at once. These tumors are so accessible to the finger that this procedure can readily be accomplished, provided their capsule has never undergone inflammation. In all of these cases the vagina should afterwards be kept carefully cleansed by antiseptic washes, and the inflammation of the cervical mucous membrane, which usually accompanies these tumors, should receive proper treatment.

(5) *Myomatous Degeneration of the Uterus.*—The uterus sometimes seems to be overwhelmed with fibroids filling up the interstices everywhere, and even to harbor at the same time every variety of tumor heretofore considered. When such a condition exists, it is not to be expected that medicinal means alone will be of much use, nor can the surgical treatment of each, individual, diseased mass be contemplated, but if anything is to be done, it must be the entire extirpation of the affected organ. As these cases cannot always be clearly diagnosticated, the surgeon must be prepared to vary his original course of action during the progress of an operation. He may commence with the expectation of removing only a pedunculated fibroid, or even an ovarian tumor, but will sometimes end by extirpating the entire uterus and its appendages. I will relate the following case:—

On August 8, 1875, I visited, with Dr. Kurtz, Mrs. J. A. D., of Reading, Pa. She was 44 years old, had menstruated at 15 years of age, and had always been regular. When 27 years old she had married, and had had two children, and one miscarriage between them. In 1872 menstruation had become more free, and in the summer of 1874 she had had two or three attacks of bleeding during the menstrual intervals. In 1872 she had first noticed a tumor in the right groin. It was hard and movable, and fell over on turning her body. For two years its increase in size had been gradual, but during the last twelve months very rapid. As the tumor enlarged, her general health failed, and she rapidly emaciated.

At the time of my visit, the abdominal enlargement was equal to that of an eight-months' pregnancy. It was irregular in shape. There appeared to be two tumors, or one with a deep sulcus dividing it. The mass was hard, but slightly elastic, and upon the left side of its fundus there was a harder knob the size of a walnut. The two lobes were movable on each other. The uterus occupied the back part of the pelvis, admitted the sound two-and-a-half inches, and was not much influenced by manipulating the abdominal growth. While the sound was in the uterus, I discovered still another and much harder mass in the superior strait of the pelvis, which I diagnosticated as an intra-mural fibroid, but had some doubts in consequence of the abdominal enlargement having masked the examination. The diagnosis was obscure, but I inclined to the opinion that the abdominal tumor was pedunculated, and hence rather favored an operation.

The patient's health continuing to fail, she solicited relief. September 1, 1875, I visited Reading, and met Drs. Kurtz, Brooke, Ulrick, Dundor, Kuhn, Coblentz, Cleaver, Weidman, Brodhead, and student Ellis Kurtz. The division of the tumor had now disappeared, and the mass was more consolidated. An incision seven or eight inches long was made below the umbilicus through a very attenuated abdominal wall. On exposing the tumor, the characteristic mahogany color at once disclosed its uterine nature, and further examination developed its real character: fibroid degeneration of the body of the uterus. There being no adhesions, the whole mass was easily rolled from the cavity of the abdomen. The body of the uterus was now found to be occupied by intra-mural fibroids, while the cervix was normal. Both ovaries were seated on the lower portion of the enlarged uterus; the right one being healthy, and the left cystic, and as large as a walnut. A strong needle was now armed with a double ligature of strong plaited English silk cord, and with it the cervix uteri was transfixed just above the insertion of the vagina and below the ovaries. Each ligature was securely tied on its respective half of the cervix, and each was again made to encircle the whole cervix and firmly secured. The tumor, consisting of the uterus and both ovaries, was now cut away, leaving a large button beyond the ligature. To make it doubly safe the stump was embraced in Atlee's clamp, and maintained outside. The cervical canal was plainly seen on the face of the cut pedicle, into which a probe was passed about three-eighths of an inch, and a finger introduced into the vagina entered the os tincæ and felt the grasp of the clamp. The return circulation of the tumor, which escaped on excising it, was prevented from entering the abdominal cavity by protecting sponges. The wound was closed with iron-wire sutures. The patient made an excellent recovery, and now enjoys good health.

In considering the propriety of extirpating the uterus by abdominal section, we must judge each case by itself. The condition of the pelvis, vagina, and cervix uteri, is of primary importance. If the cellular tissue is indurated in consequence of inflammation or other cause, or the vagina shortened and rigid, or the cervix occupied by fibroid deposits, it will not be a case favorable for operation. If, however, the pelvis is free from morbid deposits, the vagina long or extensible, and the cervix in a normal state, the chances of life may be considered almost equal to those of ovariotomy.

(6) *Fibro-cystic Tumors of the Uterus.*—The fibro-cystic tumors of the uterus, as far as my observations go, are developed upon the exterior surface of the organ, and are usually pedunculated. They are constituted of fibrous tissue, and are more or less cancellated in structure, and in consequence of their greater impressibility are called soft fibroids in contradistinction to the hard tumors heretofore considered. They grow sometimes to an enormous size. These tumors, in my opinion, are entirely beyond the influence of ergot, while they seem at times to be controlled in their growth by muriate of ammonia. I have had no experience in the treatment of uterine fibroids by means of galvanism, but I should suppose that this would be the kind of tumor most amenable to such an agent. There are, however, surgical means, both palliative and radical, which I have employed with benefit. The palliative treatment consists in penetrating the abdominal wall with a long, large-sized trocar and canula, thrust into the centre of the tumor, withdrawing the trocar and passing a strong sound through the canula, and with it breaking up the interior, cancellated structure in every direction, and drawing off all the fluid possible. Usually after such a proceeding the tumor will diminish in size to a considerable extent. The operation, at proper intervals, may be repeated. As this treatment is original with myself, I must ask permission to illustrate it with a case:—

On April 22, 1863, I was consulted by Mrs. A. E. S., of Washington City, D. C. She was 42 years old, had commenced menstruating at 14 years of age, and had been married at the age of 17. She had had three children, the youngest then 18 years old. About four weeks before seeing me, she had been seized with very acute pain in the right groin, which lasted for twenty hours, and was only relieved by strong opiates. This was followed by an enlargement of the right side. She was a fine, healthy-looking lady, disposed to corpulency, and exhibited no unusual abdominal prominence. An elastic, cyst-like, smooth tumor was detected occupying the hypogastric and right inguinal regions, and rising above the umbilicus. It was at that time diagnosticated to be an ovarian tumor, and she was advised to let it alone.

September 24, 1868, she consulted me again. The abdomen then was very much larger than that of a woman at the full period of pregnancy. It was smooth, elastic, compressible, semi-fluctuating, and of uniform shape. The uterus was normal in size, and movable, independently of the mass. In company with Dr. David Burpee, I passed the large trocar into the tumor below the umbilicus, but no fluid escaped. The sound was then introduced through the canula, and passed round in several directions. It was very evident that in manipulating with the sound many fragile septi were broken up, which proved to be the walls of cells containing fluid. Two or three gallons of fluid, stained with blood, were removed in this way, and it coagulated on exposure to air. The operation was followed by no unpleasant symptoms, and afforded great relief. Up to this time the case is reported in detail in my work on the Diagnosis of Ovarian Tumors, page 285. Subsequently the tumor was invaded in the same way at distant intervals three times, and each time with beneficial results—the last being in March, 1871. I saw the patient in November, 1872, when her general health was good, and her size very much diminished, although the tumor was still there. During all this time she had used the muriate of ammonia internally, and the combined treatment had had a very happy effect on her condition. Letters from her assure me that she still remains in comfortable health, that the size of the tumor is not nearly so great, and that its further development is probably arrested.

I have treated other cases of fibro-cystic tumor of the uterus in the same way with similar results, but have never entirely cured them by

these means. In one case, I cut up the interior structure with a small knife introduced through the large canula, and afterwards injected acetic acid. This was followed also by a decided diminution of the tumor, and by no unpleasant consequences.

The only radical cure for these tumors I believe to be extirpation. In their removal, the surgeon must keep in mind their peculiar pathological relations with the uterus and with the peritoneum, as these differ materially from those of ovarian tumors. As far as my observations have gone, the fibro-cystic tumor originates from the wall of the uterus at the junction of the cervix with the body, at or just below the point where the peritoneum is reflected from the uterus to form the recto-vaginal *cul-de-sac*. As the tumor enlarges it raises the pelvic peritoneum above it, and, dissecting it from its natural attachments, elevates it into the abdominal cavity far above the pelvis, so that a real peritoneal *cul-de-sac* almost surrounds the enlarged tumor between the umbilicus and pubes. The tumor now is covered by a peritoneal coat above, while its pelvic portion is free from peritoneum. The reflected peritoneum, therefore, acts like a coronary ligament in binding the lower portion of the tumor in the pelvis. To illustrate the operation, I will relate the case of Miss E. E., aged 57 years. The same case is detailed for another purpose in the work referred to above, page 279, but the manner of operating is omitted:—

On June 5, 1868, in the presence of Drs. Mitchell, Brinton, Thompson, and Keen, and assisted by Drs. Drysdale and Burpee, an incision seven inches in length was made through the linea alba down to the tumor. Passing my hand through the incision, I found the tumor to be adherent to the abdominal wall; but these adhesions were readily broken up. I now particularly explored the interior of the left side, in the previously ascertained locality of the elevated uterus, but soon encountered an additional tumor, resembling an hypertrophied spleen and filling up the whole left side from the hypochondrium down into the iliac fossa. In carrying on the investigation downwards, over the large tumor, my hand was interrupted in its descent by a *cul-de-sac* of reflected peritoneum, extending around the tumor midway between the umbilicus and pubes, and firmly fixing it in position. It was, therefore, plain that the fundus of the tumor was covered by a coat of peritoneum which had been lifted from the pelvis by its development upwards. The membrane was vascular and thickened. I next cut boldly into the tumor, in the line and to the extent of the external incision, and, passing my hand into the gap thus made, broke up the whole interior of the mass, freeing it of one or two gallons of yellowish fluid, which coagulated on exposure to air. After thus reducing the size of the tumor, I succeeded in shelling off the whole peritoneal coat, to which were attached several folds of intestines, and by this means relieved it of all points of attachment in the abdominal cavity. The entire mass was now readily dislocated and turned out of its bed. It was found to be attached by a fibrous pedicle, an inch to an inch and a half thick, to the uterus on the right side, at a point between the insertion of the vagina and that of the uterine peritoneum. The pedicle was short, almost sessile. It was transfixed by a strong double ligature, which was tied both ways and also encircled the whole pedicle. The tumor was then excised, so as to allow a large button beyond the ligature.

The remaining tumor now presented itself at the opening. It sprang from the posterior surface of the left broad ligament just where it joins the posterior part of the uterus. The Fallopian tube coursed along in front of the pedicle, was wrapped around it, and its fimbriated extremity rose up on the tumor, and was attached to it. Several adhesions to the walls of the abdomen were broken up, and the tumor was turned out. The pedicle was very short, but was clamped, the Fallopian tube being included, and the tumor was removed.

The abdomen was afterwards carefully cleansed with soft sponges, as well as the pelvis, which was nothing but a raw surface having no peritoneal lining. The right ovary was found to be healthy, the left being absent and evidently involved in the small tumor. A large amount of loose peritoneum, which had been removed from the large tumor, now occupied the lower portion of the abdominal cavity. It had contracted very much, and appeared more thickened. It was allowed to arrange itself. The uterus was enlarged to more than twice ts normal size. On its anterior wall was a small sessile subperitoneal fibroid. I opened its capsule, enucleated, and removed it.

The clamp was arranged across the middle of the wound, the ligated pedicle in the lower end, and five wire sutures were introduced above and five below the clamp; the fundus uteri occupying a position against the interior surface of the wound between both pedicles. Several ounces of blood were lost, but not sufficient to affect the pulse. One vessel was controlled by torsion, and one by silk ligature, cut short and dropped in. The large tumor was fibro-cystic, weighing thirty-five pounds. The small one was an ovarian fibroid, and weighed over five pounds. The patient made an excellent and rapid recovery, and is now in the enjoyment of perfect health.

In presenting this subject for discussion, I am aware that I am open to criticism for having made such an arbitrary subdivision of fibroid tumors of the uterus. It is, however, apparent that this has been done for practical reasons. A much simpler classification would have been into subserous and submucous, or *extra-muscular*, and interstitial or *intra-muscular*. But as the question to be considered was the *treatment* of fibroids, I preferred arranging these tumors as we find them in patients, so as to make the paper purely clinical and practical. In making the above division, it must not be inferred that each case can be classified under one or other head, for several or even all forms of fibroids may be present at the same time. According to my observation, however, the intra-muscular tumor is most likely to be solitary, while the extra-muscular is more frequently multiple.

As a consequence of the limited time allotted to this paper, and which has already been exceeded, I have viewed this subject only from a personal stand-point. In omitting to mention the various modes of treatment of which I have no experience, I mean no disrespect or disparagement to any of my medical brethren, who, perhaps, may have had better success than myself. These methods, it is hoped, will be stated by their advocates. With regard to the use of one agent, which has recently been extensively used, I may be excused for repeating that I commenced the use of ergot in 1845 in the treatment of fibroid tumors, and have continued to employ it beneficially ever since. I have, also, for many years, used muriate of ammonia alone, and in connection with ergot, and with such results as have satisfied me of its value. The dose is ten grains three times a day. A solution of one drachm to one pint of water is used twice a day as a wash to the abdomen and to the vagina, and an apron of silk oil-cloth is worn next to the skin. Neither patient nor physician should tire in its use, using it for months and even years, if the tumor does not disappear. I am satisfied that it often arrests the growth; so does ergot. It sometimes causes its entire disappearance; I have yet to see this result from ergot alone, except in mechanically expelling polypi. It sometimes fails to produce any appreciable results; so does ergot. I attribute the influence of muriate of ammonia to its alterative, resolvent, and sorbefacient power, as well as to its alkaline properties. I am well aware that the remedial power of muriate of ammonia has been

denied on the ground that inflammatory or plastic deposits have been mistaken for fibroids. I do not pretend to possess any more diagnostic tact than others, but the same remark will apply to all other remedies and to all other persons. Even if it accomplishes so much under an error of diagnosis, it certainly is a great boon to suffering humanity.

I now present the following propositions, which will throw the whole subject of treatment open to discussion:—

I. Fibroid tumors of the uterus, although frequently unaffected by treatment, are sometimes cured, and often controlled in their growth, by medicinal and other agents.

II. Fibroid tumors of the uterus which are entirely harmless to the patient, should never receive surgical treatment involving the least danger.

III. Extra-muscular, submucous tumors usually demand surgical treatment.

IV. Hemorrhage, caused by a fibroid, uncontrollable by other means, may be, and should be, arrested by the knife.

V. In the surgical removal of fibroids, it is of the greatest importance to extirpate the living tumor.

VI. When the living tumor cannot be removed, as is usually the case when the capsule has undergone inflammation, antiseptics must be diligently employed.

VII. Extra-muscular tumors of the subperitoneal variety, when involving health and life, should be removed by abdominal section.

VIII. In cases of recurrent fibroids, it is justifiable, under certain circumstances, to amputate the inverted uterus, or to remove the organ by abdominal section.

IX. In exceptional cases of uterine fibroids, extirpation of the uterus by abdominal section is warranted.

X. As a general rule, in all cases of fibroids which destroy the comfort of a patient, or hazard life, and are not amenable to other treatment, surgical interference is to be commended.

Discussion on Dr. Atlee's Paper.

After the reading of the preceding paper, the President, Dr. Robert Barnes, of London, said:—This is a very important subject, and one upon which we need all the light possible to get. We need not care so much about the successful cases as about the failures, and also the reasons for the failures. We should not rush into an operation when there is no hope of benefit. From the distinguished physicians present, I think that some ideas may be developed in a surgical way that will be of use to humanity.

Dr. John L. Atlee, of Lancaster, said:—I believe that abdominal section for the removal of fibroid tumors has been decided upon as a necessity in some cases. I once met with a case in which the enlargement of the abdomen was equal to that of an eight months' pregnancy, and was hard on the right side. I diagnosed an ovarian tumor. Two days afterwards the operation was performed. On opening the abdomen I encountered a dark-brown cyst, such as I had never noticed in cases of the kind. I drew off six pounds of fluid, which looked like an infusion of coffee-grounds, and succeeded, with some difficulty, in surrounding the pedicle with a clamp. On examining the tumor, I found it to be of unusual character, and uterine. It weighed, in addition to the six pounds of fluid drawn off, about as many pounds of a solid mass. Hemorrhage had occurred in the tumor on one side, and had bent it over the

uterus until it was of a half-moon shape. I confess that I was disappointed in my diagnosis, but the patient did well. If through an error in diagnosis I was successful in removing such a tumor, I do not see why it is not a legitimate operation to perform abdominal section for fibroid tumors, as well as in ovariotomy. In another case there was an ovarian cyst on the right side, and a subperitoneal uterine fibroid weighing six pounds on the left. Both pedicles were included in the same clamp, and the woman did well.

Dr. Alexander Dunlap, of Springfield, Ohio, said:—The treatment of fibroid tumors is now on trial before the profession. I have been watching the question for thirty years, and my experience does not entirely coincide with that of the author of the paper which has been read. Many tumors require no operation at all, for after attaining a certain size some disappear, while others stop growing, and give us no further trouble. I think that if the mind be withdrawn from the diseased organ, in nine cases out of ten the tumor will remain quiescent and give no annoyance. I have known of cases in which the tumor was as large as a uterus at full term, without giving much inconvenience. Fibroids often cause hemorrhage, a thing to be guarded against. I have found that ergot contracts the muscular coat, and cuts off the source of blood from the tumor. I differ also as to methods of operation. Dr. Atlee uses the knife to remove the tumor; I prefer the *écraseur*, because it prevents hemorrhage. In some cases enucleation is effective, but I have lost two cases from want of proper drainage, septic inflammation having supervened. I would propose a new method of dealing with the pedicle in cases requiring the removal of the uterine tumor. This consists in dissecting the peritoneum off of the lower half of the tumor, and in removing the latter by the *écraseur* very close to the os internum. Strong silk threads are then passed at various points through the edge of this cup-shaped peritoneal covering. Next the cervical canal of the uterine stump is dilated, and a small speculum introduced per vaginam. Through this the ends of the silk threads are passed, and the peritoneal coat is drawn by them through the uterine canal into the vagina. Thus no raw surface can remain within the abdominal cavity, for the stump is covered by peritoneum, and all discharges become external. In some cases of hemorrhage I have found it of advantage to lay the patient on an inclined plane, with the head low down, so that the tumor can be pressed from the pelvic into the abdominal cavity; the proceeding is very easy in these cases. I have never been able to stop the growth of a tumor by ergot, but it is of use in checking hemorrhage.

Dr. G. Kimball, of Lowell, Mass., said:—I concur in the opinion of Dr. Dunlap, that these tumors should be let alone, except when it is absolutely necessary to use the knife. They sometimes disappear spontaneously, and it requires good judgment to tell what cases need operation. Such as do not involve the vagina or the neck of the uterus are the only ones that can be operated upon. A surgeon would be almost guilty of homicide who should attempt an operation in some cases in which the fibroid fills the vagina and invades the cervix, and in which hemorrhage would inevitably result, for there would then be no pedicle which could be ligated. In one case I removed the womb on account of a sessile subperitoneal fibroid, and secured the pedicle with a silk ligature the ends of which were brought out externally. For eighteen months the ligature ends remained *in situ*, and then disappeared internally, as the patient averred. Instead of the ligature I now use the wire *écraseur*, which I fasten externally by adhesive straps, after searing the stump with the hot iron. In this manner I am able to control all hemorrhage without having much of a pedicle left. Very few cases authorize extirpation of the uterus. I have seen good results from ergot, but none from the muriate of ammonia in subperitoneal fibroids. But one of my cases got entirely well after using for a year intra-uterine injections of a solution of eight grains of iodide of potassium in an ounce of water.

Dr. E. R. Peaslee, of New York, said:—Fibrous tumors should be consi-

dered apart from other tumors. They either produce hemorrhage or they do not, and this depends greatly on their site. When there is no hemorrhage I do not consider that we have any right to interfere. In the treatment of these growths, I have used the muriate of ammonia with good effect, but I do not think that we can expect much from ergot, except in cases of interstitial tumor. It might possibly affect the uterine muscles, and cut off the nutrition of a subperitoneal fibroid, but I have little faith in most of the ways suggested for its use. I would reject the use of ergot entirely except in cases in which contraction was an absolute necessity. There is no hemorrhage so great that it cannot be stopped for a time, and this time is important, as it gives a chance to think whether the case really needs a surgical operation. Women very rarely die from hemorrhage in these cases, but more frequently from septicæmia. In ordinary cases of hemorrhage I give ergot in combination with the tincture of the ferric chloride. In severe cases I introduce a tent into the cervix, and keep it *in situ* by means of a vaginal tampon. When septic symptoms show themselves, I consider repeated, intra-uterine, disinfectant injections as of paramount importance. I regard it as a safe rule not to interfere with fibroids. In regard to cutting into a fibroid, I have found that an incision through its mucous capsule is valuable in arresting hemorrhage, but I have never used enucleation because I am afraid of subsequent bleeding. In such cases I use the ligature and antiseptic washes. I would suggest to Dr. Atlee instead of the term "recurrent fibroid," which he has used in his paper, that of "multiple fibroid." In the discussion of this subject, fibro-cysts should be separated from fibroids proper; the former generally spring from the posterior wall of the uterus, and drag the organ upward, elongate it, and bend it forward; this does not occur in cases of simple fibroma, and constitutes a diagnostic point. I do not think that we are justified in removing a fibroid unless the patient is in such a condition that she will die without the operation. With fibro-cysts, the operation is often necessary, and if, in a case of ordinary fibroid, life were threatened, I should not hesitate to extirpate the uterus.

Dr. H. Lenox Hodge, of Philadelphia, said:—No reference has been made to what I consider very important, namely, accurate statistics of operations for the removal of these tumors by abdominal section. It would be of great value if each surgeon would state how many times he had operated, in how many cases the operation had been successful, and in how many it had been fatal. This has been done in regard to ovariotomy, and the same reasons apply for doing it in this case. Dr. Péan, of Paris, has published such statistics. His results are very favorable. They as yet stand alone. No one else has approached the success which he reports. I have myself, as yet, never operated in a case of this kind, and have never met with a case which seemed to require it. On the other hand, it would also be of value to know the history of cases which have not been operated upon. I have seen many of these tumors of the uterus, and have the record of some of my father's cases, dating back many years, which are still under my observation. In my experience, the number of deaths resulting from such tumors when let alone is very small; and, as the patient approaches the age of fifty years, the tumors often begin to diminish. In some of my cases, no trace of the old tumors can now be detected. One of the dangers, dreaded by some, is inflammation, resulting in septicæmia; this I remember to have seen in only a single case. Another danger is hemorrhage; this I have always been able to control. I have seen very good results follow the use of hypodermic injections and suppositories of ergot. The ergot, according to my observation, acts well in all the varieties of these tumors, including the subperitoneal. I believe that it acts by contracting the bloodvessels, rather than the muscular tissue, of the uterus. There is a remedy, however, which is far superior to ergot. It is a surgical one, and consists in pushing up the tumors out of the cavity of the pelvis, and maintaining them, by proper pessaries if need be, above the brim of the pelvis. This relieves the dysuria and tenesmus so common from pressure of the tumor on

the bladder and the rectum; but more than this, it lessens in a most remarkable manner, or arrests, the hemorrhage. The cause of this hæmostatic effect is somewhat obscure and difficult to explain. It seems probable, however, that there being no longer pressure from the firm pelvic walls, the circulation becomes unembarrassed, and, the blood returning by the veins, the congestion of the uterus is diminished.

The President, Dr. ROBERT BARNES, of London, said:—We must have adequate reasons for these operations. The question is, whether we should allow patients to die, or use all the means at our command to save life. This discussion will be a help to all of us. In my own practice I last year lost three patients from a sort of necrosis which supervened upon the incision of the capsule of submucous tumors, and an attempt to enucleate them. This unfortunate experience has made me very shy of undertaking any such procedure unless the whole tumor can be removed at one operation. If the tumor were too large to be approached by the vagina, I should advocate gastrotomy as soon as the woman's life was threatened.

Dr. ATLEE, in reply, said:—I beg to return thanks for the attention given to my paper. All of the points which I have advanced have been sustained by the very distinguished gentlemen who have taken part in the discussion. Physicians are bound to aid a patient when in extremity, and should employ the means which they know to be of use; we have no right to let a disease alone; our business is to relieve the patient.

THE THREE MOST IMPORTANT OBSTETRICAL INSTRUMENTS.

BY

T. LAZAREWITCH, M.D.,

PROFESSOR OF CLINICAL MIDWIFERY AND DISEASES OF WOMEN, AND DIRECTOR OF THE GYNÆCOLOGICAL CLINIQUE, IN KHARKOFF, RUSSIA.

[COMMUNICATED BY THE SECRETARY.]

A BLUNT hook,[1] a parallel forceps, and an embryotome, devised by Prof. Lazarewitch, and presented by him to the Congress, under this title, are offered to the Section on Obstetrics.

The Blunt Hook is bent at both ends in the same direction, and has a hole drilled in one end, and two holes in the other. Apart from the uses to which the ordinary, obstetric, blunt hook is devoted, this one possesses the important advantage of enabling the practitioner to replace a prolapsed funis, and to carry a fillet around the thigh of the child, or a noose around its ankle.

The Parallel Forceps weighs only one pound, has narrow blades, is but eleven inches in length, and when closed gives a divergence of two and a half inches at the hollow of the blades. The handles lie parallel to one another, and are locked by lateral contact. The lock, consisting of a tenon and mortise, is so loose as to permit freedom of movement to the child's head. By the shortness of its handles, this instrument cannot exert much compressive or extractive power. To compensate for this deficiency, a strong silk loop is attached, either just above the lock when compression is needed, or at the ends of the handles when merely powerful traction is called for. By this loop, traction can be made also in any direction, and the forceps converted into a lever whose fulcrum is represented by the hand at the handles. The inventor attributes the following advantages to his parallel forceps:—

"Either half may be introduced first with equal facilities for locking.

"After the first blade is introduced, the way is not obstructed against the second, as it is with the crossing forceps, which is especially important in cases in which the head is high up in the pelvis, and the vagina imperfectly dilated.

"The locking is effected with perfect ease, and without risk of pinching the soft parts of the mother, which are quite clear of the lock.

"Whatever force of traction may be applied, in all cases immediate pressure of the head with the blades may be avoided on account of this possibility of accommodating themselves to the head and the mother's parts. This cannot be so perfectly effected by any other forceps."

The Embryotome consists of a hollow shaft, armed with a steel beak at one end, and with a screw at the other, which opens and closes the beak. The instrument is introduced closed. The beak is then opened

[1] [An abstract, only, of Professor Lazarewitch's paper is here inserted. The original manuscript, with elaborate illustrations and samples of the instruments described, is deposited in the Museum of the Obstetrical Society of Philadelphia.—EDITOR.]

and made to bite into the cranium. By turning the shaft on its longitudinal axis a portion of the skull is then torn off. By repetitions of this process the whole vault is broken up. For this instrument, Prof. Lazarewitch claims not only the property of lessening the bulk of the head, but that of acting as an efficient tractor, and of being available for severing the neck, or any portion of the body, in a difficult cross-labor.

ON THE NATURE, ORIGIN, AND PREVENTION OF PUERPERAL FEVER.

BY

W. T. LUSK, M.D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF CHILDREN IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE total number of deaths in the city of New York for the nine years from 1868 to 1875, inclusive, was 248,533. Of these, 3342 were deaths either from diseases complicating pregnancy, from the accidents of child-bearing, or from diseases of the puerperal state; or, in other words, very nearly one in seventy-five of all the deaths occurring during that period, was the result of the performance of what we are in the habit of regarding as a physiological function.

A careful study of the records preserved by the Health Department of the city has enabled me to classify these 3342 deaths into:—

(1) Those due to child-birth proper, under which head I would place deaths from shock, from protracted and unusually severe labor, from convulsions, from flooding, from rupture of the uterus, and, for the sake of convenience, those from extra-uterine pregnancies;

(2) Deaths from eruptive diseases, from phthisis, and from the various non-puerperal, inflammatory disorders complicating child-birth. A few cases recorded as typhus, typhoid, and intermittent, I have included under puerperal fever, on account of certain inherent difficulties in the differential diagnosis. Should exception be taken to this action, I have only to state that the entire number thus recorded is much too small to palpably affect any conclusions which this report may contain;

(3) Deaths from a variety of diseases, occurring during pregnancy, in which the pregnant state was, in all probability, an active cause of the unfavorable result;

(4) Deaths from miscarriage (I use the term as I find it employed by the majority of physicians, in their reports, to designate all cases of interrupted pregnancy during the first six months), in which either intercurrent affections, the lack of proper medical assistance, actual want, or criminal malpractice, have been the chief factors in determining the fatal issue. To be sure, in many of these instances, death is due to the supervention of peritoneal complications, septicæmia, and pyæmia, assimilating them closely to cases of puerperal fever. I do not, however, include them under puerperal fever, because their origin is not involved in mystery. Two words tell the whole story, viz., neglect and violence. The explanatory term, retained placenta, testifies to the one, and the certificate of the coroner to the other. We all know how common fatal cases of metria are, in large hospitals, after delivery at full term. After abortions, on the contrary, they are rare. Thus the uterine wards of the Bellevue Hospital have always contained a large complement of women, who have entered the hospital in a very low state induced by some of the sequelæ of abortion. Of these, in nine years, two only have died. Dr. George K. Johnston

reports in seven years, in the Rotunda Hospital in Dublin, but one death in 234 cases of abortion, and that the result of mitral disease of the heart. I have, for the sake of convenience, exhibited the precise proportion of deaths due to each of these several causes in tabular form. Collectively they will be seen to have numbered 1395 cases, or about 42 per cent. of the entire number.

TABLE I.—*Deaths occurring during pregnancy, confinement, and the puerperal state, in New York, between the years* 1867 *and* 1875, *inclusive, excluding those from metria.*

[1] Under *childbirth* are included deaths from shock, from intercurrent non-puerperal diseases, from complications, such as tumors, cancer, disease of the heart, and the like, and all cases reported under childbirth which proved fatal within twenty-four hours of delivery, not elsewhere mentioned.

[2] A large number of deaths from *uræmia* are reported, in which it is not stated whether convulsions existed or not.

[3] Under *miscarriage* are reported all cases in which pregnancy was interrupted previous to the seventh month.

[4] Under *pregnancy* are given deaths, from non-puerperal causes, in which pregnancy existed and probably contributed to the fatal issue. The number of deaths from phthisis is specifically given in the report, as are those from smallpox, scarlatina, and erysipelas, subsequent to 1870.

(5) There thus remain 1947 cases which, variously reported as puerperal fever, puerperal peritonitis, metritis, metro-peritonitis, phlebitis, phlegmasia dolens, pyæmia, and septicæmia, furnish the subject for special inquiry in this paper. All these varieties we will term briefly puerperal fever, attaching to the term, however, no special significance. The diagnosis of anatomical lesions from clinical symptoms alone, unverified by post-mortem examination, is, in the most experienced hands, only approximative. As usually reported by the practitioner, these lesions reflect for the most part his individual theory, or early training. As a matter of convenience then we propose to employ the name puerperal fever as a general term to cover all the febrile conditions peculiar to the puerperal state.

In the 1947 cases of puerperal fever, I have included cases of patients reported to have died of puerperal mania, the non-febrile form rarely proving speedily fatal. That this rule is not universal, I readily admit. Thus, I remember a case occurring in the Bellevue Hospital, in which the

maniacal patient was confined in one of the cells of the hospital. During the night, she got out of bed and broke the windows. The night was bitterly cold. The patient sat up in her night-dress with the cold air streaming in upon her. On the next morning she was seized with pneumonia, and died. A few cases of death, too, reported from insane asylums do not belong in this category. Giving to the term, puerperal fever, then, this broad significance, we find that in nine years it was the cause of nearly one one-hundred-and-twenty-seventh of all the deaths occurring in the city. It is to be regretted that the returns of births in the city are imperfectly rendered. The actual number of births during the last nine years may, however, be roughly set down at 284,000. This estimate is based upon the assumption that the natural birth-rate is thirty-three to the thousand,[1] an estimate which errs upon the side of liberality. The total number of deaths then to the entire number of confinements would be at least in the proportion of one to eighty-five, or, from puerperal fever alone, in the proportion of one to one hundred and forty-six. These figures proclaim more eloquently than any words can do, the necessity of frequently reviewing the state of our knowledge as to the nature of puerperal fever, and of inquiring as to how far it is due to causes which are amenable to human control.

At the outset, it is proper to recall that, as the various names applied to puerperal fever indicate, it is, with rare exceptions, associated at some period of its progress with certain inflammatory processes which have their starting-point in the generative apparatus. The lesions most commonly found in post-mortem examinations consist of catarrhal inflammations of the mucous membrane lining the vagina and uterus, with simple ulcerations, or those presenting a diphtheritic character, inflammation in the pelvic cellular tissue, metritis, local and general peritonitis, inflammation of the lymphatics and veins, thrombosis, pleuritis, pericarditis, valvular affections of the heart, abscesses, and other destructive processes in the parenchymatous organs, and purulent collections in the joints. As a rule, the occurrence of one or other of these inflammatory processes is synchronous with the first outbreak of fever.

When we come to analyze our cases of puerperal fever, we find two general groups, the one *infectious*, the other *non-infectious*.

I. *The Non-infectious Group.*—Every one who has seen much of hospital practice, has of necessity observed instances of puerperal inflammations and febrile conditions, often of a severe type, which have possessed this distinctive peculiarity, that they have in no wise visibly affected the health of puerperal patients in their vicinity. They possess this feature in common, viz., that in them the symptoms of blood-poisoning are absent, or are present only to a subordinate extent, and as a late feature of the disease. The nature of cases belonging to this group may be best expressed by an examination of the known causes which call them into existence. I give the following from a vast number of recorded cases, without pretending, however, that they exhaust the list:—

(1) Inflammations may arise from traumatic injuries, such as rupture of the cervix uteri during labor, those resulting from unskilfully performed operations, and from the bruising or crushing of the soft parts of the mother in long labors, especially in cases of moderate pelvic deformity.

[1] The census for 1870 gives to New York a population of 942,292. The average of annual increase from 1860 to 1870, was 15,000. I have taken 15,000 as the probable average increase since 1870. The inaccuracy in this calculation is not considerable enough to materially affect the proportions.

(2) The imprudence of patients or their nurses. Thus I have frequently been able to trace, in hospital practice during the winter season, severe cases of cellulitis, pelvic peritonitis and general peritonitis, to the patient's getting out of bed, dripping with perspiration and clad only in a night-dress, and going thus bare-footed over a cold uncarpeted floor to the water-closet. Even in private practice, like instances of wilfulness are not unknown; nurses too, especially those who are reputed by the fair sex to know more than any doctor, are fertile sources of trouble.

(3) Moral causes are frequently effective in producing serious disturbance. In studying the records of Bellevue Hospital for the year 1873, I was greatly impressed by the fact that in 240 deliveries in married women there were but two deaths from puerperal fever, while in 209 in non-married women there were thirteen deaths. From the Bureau of Vital Statistics I learn that one-eighth of the deaths from puerperal causes occur among unmarried mothers. Dr. Johnston dwells much upon a similar state of affairs existing during his mastership at the Dublin Rotunda Hospital. In a paper on "The Genesis of Puerperal Fever,"[1] I reported an instance in which five women were confined in the same ward, by the same attendants, and under absolutely the same conditions, with the exception that one chanced to witness the sudden death of a patient from rupture of the uterus. While the other four women did well, this one, after a period of great mental agitation, developed peritonitis and died. It has been suggested that such cases occur only in the records of hospital practice. This is not so. During the past summer I saw in consultation, in a remote and very healthy rural district in which puerperal diseases were unknown, a case of severe fever, lasting eight days, which was traceable to the mother's anxiety and fret over the illness of one of her children. Dr. Alfred Wiltshire, of London, after writing to me an account of a poor woman who died in less than twenty-four hours in collapse, brought on by a rough remark from her husband, adds, "I have seen many other similar though less severe cases, and I confess that my sympathies are deeply touched whenever I have to attend women who have cause for depression during labor."

(4) I have, in a number of cases, had occasion to notice the influence of old adhesions existing between the serous coverings of the pelvic organs, due to a by-gone peritonitis, upon the pregnant and puerperal states. The two following instances will serve as illustrations:—

The first was that of a young wife, who, a few months after her marriage, had a miscarriage. Unfortunately a portion of the ovum remained in the uterus, where it became the source of protracted hemorrhage and some febrile disturbance. A couple of months later, however, the offending body was removed, after preliminary dilatation of the os, by a distinguished physician who was summoned in consultation. A sharp attack of pelvic peritonitis followed, from which, however, the patient so far recovered as to enjoy a period of reasonable health. Then she became again pregnant. In the sixth month of gestation she began to lose flesh rapidly, and had repeated chills, with profuse perspirations, and a continuously high temperature with evening exacerbations. Living at the time, however, in a New Jersey rural district, her symptoms were attributed to malarial influences. I was consulted concerning the case in the eighth month, and on hearing the history predicted an inflammation of the kind under consideration; and found, as I had anticipated, on examination, a large and distinct tumor reaching from the left iliac fossa to the upper margin of the kidney, which was evidently the product of chronic

[1] American Journal of Obstetrics, vol. viii., Nov. 1875, p. 371.

cellulitis and peritonitis. Soon after, she gave birth to a premature but living child. In a few days subsequent to her confinement, the lady died. Every circumstance in the clinical history pointed to the connection between the slowly developing inflammation during pregnancy and the earlier acute attack of peritonitis.

In the second case I was called to see a patient suffering from puerperal convulsions, in whom gestation was complicated by a large fibro-cystic tumor of the uterus. After administering chloroform, I dilated the os, and delivered the child by version. Hemorrhage followed, which was, however, promptly arrested. The three days following, my patient had no bad symptoms. On the fourth, she complained of pain on the left side, which gradually extended over the abdomen. Meantime the temperature rose, the pulse became rapid, and on the following day she died. The post-mortem examination showed no lesions of either the uterine cavity, the cervix, or the vagina, which were all normal in appearance. That portion of the uterus, however, which had undergone fibro-cystic degeneration, and which was found to weigh between six and seven pounds, was covered with fibrinous flakes. Everywhere the tumor was glued to the adjacent serous surfaces by adhesions of long standing, and strong, organized bands, many of them the size of a goose-quill, connected it with neighboring organs. There could be no doubt, on examining these appearances, that the peritonitis had been caused by the dragging of the heavy tumor upon these adhesions, after the evacuation of the uterus and the loss of the support of the abdominal walls.

(5) It is proper to take into consideration the vulnerability of individuals. All puerperal women are said to tremble in the balance between a physiological and a pathological condition, and it is no unfounded assertion to say that trivial causes which would be inoperative in many cases will turn the scale in others. We see this exemplified in first births, and in women who have borne children in excess. In this connection, the question started by Dr. Nathan Allen, of Lowell, as to what is "The Normal Standard of Woman for Propagation,"[1] becomes of real interest.

(6) It is to be borne in mind that the zymotic fevers, not peculiar to child-bed, may provoke in the puerperal woman the same inflammatory lesions that are commonly associated with puerperal fever.[2] This is in conformity with the well-known surgical experience that a febrile paroxysm from any cause exerts an unfavorable influence upon a wounded surface. Olshausen[3] has, however, recently shown that pelvic inflammations and peritonitis are somewhat rare in cases of scarlatina complicating the puerperal state. He likewise adds affirmative evidence to the view advanced by Braxton Hicks,[4] that scarlatina, after a long period of latency or incubation during pregnancy, can make its appearance two or three days after delivery, and, as a rule, with slight throat symptoms. The discussion in the London Obstetrical Society[5] has done much to draw attention anew to the effects of infective diseases upon the puerperal state. I should prefer, however, to exclude well-defined cases of typhus, typhoid, and scarlatina, complicating child-bed, from the

[5] Obstetrical Transactions, London, vol. xvii.

category of puerperal fever, unless coexistent local lesions should involve the pathogeny in doubt.[1]

Now as regards the foregoing dangers to the puerperal woman, it is rare that the physician is enabled to employ preventive measures; and these are necessarily not general, but those suggested by his tact, skill, and wisdom, for independent application to each case.

II. *The Infectious Group.*—The infectious form of puerperal fever is characterized by blood-poisoning. The poison is of a septic nature. The usual points of introduction of the poison are the lesions of the parturient canal. This does not, however, exclude other points of entry, and clinical experience renders it highly probable that, under certain conditions, the poison may be primarily introduced into the blood through the respiratory and digestive organs. This form is contagious, but all cases of infection are not contagious in an equal degree. It is customary for many to limit the term puerperal fever to the members of this group; as, however, there is as yet no common understanding of authors among themselves, or among practitioners in general, as to the precise limitation of the term; as, indeed, hardly any two physicians mean precisely the same thing when they speak of puerperal fever, I shall endeavor to avoid confusion by not using the term in a specific sense.

That the infectious diseases of child-birth are of septic origin, there is now abundant evidence. The question of the identity of puerperal fever and septicæmia is largely one of definition. It is a matter of ordinary experience that the retention of a small bit of the membranes within the uterus will produce fetid lochia; and, as the result of infection, a febrile condition, which, as a rule, subsides with the expulsion of the offending body and the use of disinfectant washes. A virulent form of fever is not unfrequently occasioned by retained coagula, or placental *débris*, which have undergone decomposition. I was once sent to see a puerperal patient, suffering from fever, on the fourth day following her confinement. On entering the room I found the stench intolerable; turning down the sheets, I discovered that the patient was lying in a decomposing mass, and learned that her doctor had forbidden, after the birth of her child, the removal of the soiled linen and blankets. The patient died in the third week from pyæmia multiplex.

Haussmann[2] reported a case of auto-infection in the rabbit, which terminated fatally. A portion of the membrane, retained in the left cornu, led to diphtheritic losses of substance in the lower portion of the vagina, to hemorrhagic enteritis, and to peritonitis. The same author produced death from septicæmia by injecting into the gravid uterus of the rabbit serum from the abdomen of a rabbit which had died from infection. The post-mortem examination showed the muscles filled with granules, and the peritoneum injected, but no fibrino-purulent exudation. Injections into the uterus of pus from the abdomen of a woman dying from infectious puerperal disease, produced no effect upon rabbits two weeks gravid, while in the second half of pregnancy premature delivery and

[1] There does not appear to be any very good reason why a well-marked case of scarlatina occurring in a puerperal patient should be termed puerperal fever, more than one of smallpox. Dr. George K. Johnston informs me that the cases of scarlatina occurring in the Rotunda Hospital of Dublin have never started epidemics of puerperal fever among the lying-in patients. I remember but one case of the kind in the Bellevue Hospital, and this did not affect unfavorably patients in the vicinity.

[2] Entstehung der übertragbaren Krankheiten des Wochenbettes; Beiträge zur Geburtshülfe und Gynækologie, Bd. iii., Heft 3, S. 345.

death occurred, in one case in one and a half, in another in two and a half days. In the animal which died in thirty-six hours there was commencing perimetritis and peritonitis, while in the one dying after the lapse of sixty hours the abdomen was found to contain fibrin and pus.[1] D'Espine injected into the uterus of a rabbit, which had just produced her young, pus from the abdomen of a woman who had died from puerperal disease two days before. This was subsequently followed by other injections of fetid fluids during the four days following. On the twelfth day the animal died. The autopsy revealed peritonitis, most marked in the pelvic cavity, inflammatory alterations in the vagina, uterus, and tubes, small abscesses in the body of the uterus, softened clots in the veins of the broad ligaments, and infarctions of the liver.[2] Schüller found that subcutaneous injections of septic material in female animals, during pregnancy, produced a diphtheritic, ulcerative process on the uterine surface, which determined the separation of the placenta; diphtheritic patches, likewise, were found in the cornua of the uterus.[3]

Thus we find that in the human subject, and in experiments made upon animals, septic poisons introduced into the system following or near delivery produce lesions similar to those found in puerperal fever. As a further coincidence, we notice that, as in puerperal fever, the lesions from direct, septic poisoning have nothing characteristic about them, producing in one case pyæmia, in another partial peritonitis, in another general peritonitis, in another diphtheritis, while in others the lesions are comparatively trivial—these differences being due to differences in conditions which are but imperfectly understood.

My friend, Prof. Barker, in his magnificent work on "The Puerperal Diseases," which is, as every one knows, a masterpiece in the way of clinical observation, mentions, as a distinction between septicæmia and puerperal fever, that, while puerperal fever is contagious, septicæmia is a non-contagious affection. I have the record of the following case which militates against this theory. A physician in New York delivered a woman of a putrid fœtus. The woman died of septicæmia. Two days after attendance upon the first case, he attended a second patient, who likewise died of septicæmia. Dr. Barker states that by inquiry among surgeons he cannot learn that septicæmia follows in their wake as does puerperal fever in that of the obstetrician, and yet Sir James Simpson asserts it to have been the case in his younger days.[4] The vital statistics of New York, for the last nine years, show that a sequence of deaths following confinement in the practice of individuals has become very rare, and, let us hope, that if the enlightenment of these later days has enabled the surgeon to avoid such a misfortune, in the end the same profit may accrue to the practitioner of midwifery.

But it is to be remembered that the conditions in a puerperal patient, and in one upon whom a surgical operation has been performed, are not identical. Samuel, in speaking of immunities and dispositions to septic poisoning, says:—"The statistical frequency of septic, puerperal

[1] Ibid., p. 394.

[2] Contribution à l'Étude de la Septicémie Puerpérale; Paris, 1873, p. 28.

[3] Experimentelle Beiträge zum Studium der septischen Infection; Deustche Zeitschrift für Chirurgie, Bd. vi., S. 141.

[4] "I have repeatedly heard of instances of a rapid succession of surgical fever cases and disasters in the practice of the same surgeon, while the other surgeons in the same locality had their patients recovering as usual." On the analogy between Surgical and Puerperal Fever; Simpson's Obstetric works, edited by Priestley and Storer, vol. ii. p. 19.

diseases is due to the length of the parturient canal, to the fact that through this long passage there must pass all the pathological and physiological excretions, and to the soiling of these parts with fingers, instruments, and secretions, which have become the bearers of sepsis."[1] He found, on the other hand, that it was extremely difficult to produce a progressive ichorous condition by daily painting an open stump with a septic fluid,[2] though the same was readily obtained when an infinitesimal quantity of septic fluid was injected underneath a fascia. Dr. Barker is, however, much too keen an observer to ever go far astray, and it is true, as will be mentioned hereafter, that there is a form of septicæmia which is not contagious. The only question to be raised is as to whether it is allowable to restrict the term to this form. As usual in all questions concerning puerperal fever, there is practical agreement as to facts, with divergence of opinions concerning definitions.

Until very recently the whole subject of septicæmia has been in a state of wellnigh hopeless confusion. From Gaspard and Panum, through a long list of experimenters, hardly any two have arrived at precisely similar results. Something like an approach to order has, however, been produced since it has begun to be understood that the effects produced by septic fluids vary with the quality of the poison and the method of experimentation, and that to obtain identity in the result, there must be identity in all the conditions. Thus Samuel has shown that the same organic substance produces different effects at different stages of decomposition; again that the enteritis which is commonly quoted as characteristic of septic poisoning, occurs, as a rule, in animals, when the septic fluid is injected directly into the blood, and is rare when it finds its way into the circulation through the lymphatics, as is the case usually in clinical experiences.[3] There is one experimental point of extreme practical importance too in connection with puerperal septicæmia, viz., that if the injection of a septic fluid be made directly into a vessel, toxic effects speedily follow, but are transitory, unless the amount of the fluid be large, or its virulence exceptional, or the animal very young,[4] whereas very small amounts injected subcutaneously, by developing rapidly spreading phlegmonous inflammation, resembling malignant erysipelas in man, are capable, after a period of incubation, of producing fatal results; or they may, if injected into a shut cavity or underneath a fascia, lead to the development of an inflammation of an ichorous character. In other words, the eliminating organs suffice, under ordinary conditions, to remove from the blood the same amount of septic fluid which would prove fatal if injected into the tissues.[5] To produce similar results the injections into the blood need to be repeated at intervals. This experience leads us to the conclusion that, in the tissues, septic poison possesses the capacity of self-multiplication, and that, in the local inflammation set up, a reservoir is formed from which poison is continuously poured into the circulation.

This capacity of self-multiplication, which septic fluids possess, has

[5] In some instances in which absorption from the tissues is very rapid, the effects of subcutaneous injections may be similar to those produced by injections made directly into the circulation, and the local lesion be insignificant.

recently been found to be coincident with the presence of certain organic bodies, termed variously micrococci, microspores, or sometimes, less specifically, bacteria. All carefully made experiments serve to show that, if a septic fluid be deprived of these organic bodies by boiling, or filtration, while it continues capable of producing inflammation, the inflammation is usually of diminished intensity, and remains local in its character;[1] whereas the microspores, retained upon the filter, possess all the virulent properties of the original fluid.[2] This does not alone necessarily prove that the virus resides in the microspores, for it does not exclude the possibility that both the virus and the microspores remain upon the filter.

So far, attempts at isolating the microspores and cultivating them separately in vehicles, composed of water holding in solution certain inorganic constituents necessary for their healthy nutrition, have been only partially successful in proving them to be the sole source of infection. Some experiments of Tiegel and Klebs[3] were attended with positive results, but Hiller arrived at different conclusions. He found that bacteria washed in pure water were innocuous.[4] But pure water had long before been proven by observers to be inimical to the well-being of the organisms in question. Schüller says that Hiller's experiments prove apparently that while a putrid fluid may be in the highest degree poisonous, its component parts, viz., either the fluid or the bacteria singly, are neither deadly nor poisonous.[5] The fact is that all isolation experiments are subject to what seems an unavoidable source of error. As Davaine noted, early in his observations, the physiological action of bacteria is very dependent on the constitution of the medium in which they are developed, which is in entire harmony with what is known of organisms much higher in the scale. "Many plants," says Burdon Sanderson,[6] "containing active principles, become inert when transplanted from an appropriate soil." Bucholtz, in a series of experiments designed to test the influence of antiseptics upon the vitality of bacteria, found not only a difference between those taken directly from the infusion and those cultivated in artificial fluids, but between bacteria derived from the same source and cultivated in modifications of the nutrient medium.[7] Under these circumstances, all evidence of a positive character is to be regarded as of more value than that which is purely negative.

It is, however, from the constant presence of the round bacteria in infected wounds, and their distribution through the tissues, that the argument in favor of connecting septic symptoms with the bacteria has been mainly deduced. Here the ground is sufficiently solid, and, judged by ordinary laws of scientific evidence, the pathological importance of the microspores may be regarded as established. To be sure, we find them

[1] In filtration through porous earthenware cylinders, the filtrate possesses no phlogogenic properties.

in tongue-scrapings of healthy individuals, but tongue-scrapings are poisonous if injected into the tissues. That they do not ordinarily prove so in the mouth, is no more singular than that woorara can be swallowed with impunity. Tiegel has endeavored to show that the round bacteria are found normally in the internal organs of the body.[1] If his experiments should in fact stand the test of criticism, they would only show that a few bacteria may be found in health in the liver and in the pancreas, but never in anything like the same numbers or the same general distribution, nor with the same characteristic groupings, that have been proven for a number of infectious diseases.[2] It is stated that they are sometimes absent from the blood taken during life in septic diseases. As, however, their constant presence has been confirmed in the vessels and glomeruli of the kidney, it is fair to assume that they are filtered out by those organs when the conditions favorable to their development do not exist in the blood. Again it is an open question, which awaits confirmation, whether it be not true, as Hueter claims, that the microspores do not disappear, but are taken up by the blood-globules, rendering the latter adhesive, and predisposing the blood to the stases characteristic of inflammation.[3] Zahn has shown that the inflammation in the mesentery of the frog, in the Conheim experiment, does not take place if the air is first filtered through diluted carbolic acid.[4]

As to the exact manner in which these minute bodies exercise their pernicious influence, whether they operate mechanically, or whether they produce a virus in the process of nutritive activity, or whether, as is probable, both suppositions are correct, we may safely leave as questions to be decided by subsequent investigations. It is enough for us to note that the connection between sepsis and the round bacteria is intimate and vital. Panum, who is often quoted as opposed to what is known as the Bacteria theory, admits as probable that the microsporon septicum is inoculable, appears in the blood during life, multiplies in the tissues, and, in part by production of a special poison, perhaps, and in part by mechanically irritating the tissues, excites inflammation, suppuration, and fever.[5] Bergmann, who once thought that he had found the secret of sepsis in a crystallizable substance derivable from putrid fluids, which he termed sepsin,[6] now squarely accepts the modern doctrine. Virchow has so far given in his adhesion to the new school as to say: "Especially in this connection are to be mentioned the diphtheritic process and the erysipelatous, especially erysipelas malignum. The granular deposit in diphtherically affected tissues, of which I formerly spoke, has more and more proven to be of a parasitic character. What we formerly regarded as simple, organic granules, as infiltration, or exudation, has since proven to be a dense aggregation of micro-organisms which penetrate into the tissues and cells to compass their destruction."[7] Even Billroth, who contends that what he terms a zymoid ferment is the first thing developed in the line of cau-

sation, and that the bacteria are a sort of epiphenomenon, concedes that the organisms, by their migrations, may become the carriers of the virus into the interstices of the tissues.[1] I mention the less willing witnesses to the importance of bacteria in disease: I need not recapitulate the names of a host of active advocates of the germ theory.

I have been thus explicit regarding the evidence concerning bacteria in septic diseases, because it places the question of the infectious group of puerperal fever-cases in the following position:—Experiences occurring clinically, as well as those produced upon animals, teach us that certain lesions and symptoms, similar to those we are accustomed to regard as characteristic of puerperal fever, result from septic poisoning. In a large class of cases, however, the connection between child-bed fever and sepsis has been deduced rather from analogy than direct proof. For those who chose to regard such as due to a specific poison peculiar to the puerperal state, there was really no objection. If, however, round bacteria are characteristic of septic poisoning, the question presents itself in a different light, and we have to inquire whether, in the less obvious cases, bacteria are present in puerperal fever in the proportions and groupings that we find them in other diseases due to putrid infection. Now it is precisely proof of this nature that has recently been abundantly rendered.

Waldeyer,[2] Orth,[3] Heiberg,[4] and Von Recklinghausen, found the tissues and lymphatics of the parametria filled with pus-like masses, which consisted, in addition to pus-cells, chiefly of bacteria. Bacteria swarmed in the fluid of the peritoneal cavity. In one case examined by Waldeyer, six hours after death, while the body was still warm, the peritoneal exudation was like an emulsion, and furnished an abundant deposit which consisted almost entirely of bacteria. Orth injected ten minims of peritoneal fluid from a woman dead of puerperal fever into the abdomen of a rabbit. As the animal was dying he broke up the medulla oblongata, and found in the peritoneal fluid enormous quantities of these organisms. In puerperal fever, round bacteria have been likewise found, though in less quantities, in the lymphatics of the diaphragm, and in the fluids of the pleura, the pericardium, and the ventricles of the brain. In post-mortem examinations of fresh subjects, the serous fluids, withdrawn under proper precautions, do not contain round bacteria except in cases of septic infection.[5] Orth found in the purulent contents of the vessels of the funis, in children who died of sepsis, precisely the same formations as existed in the exudations of the mother.

The presence of these germs in puerperal fever serves not only to fix cases hitherto considered doubtful in the category of septic diseases, but it affords the best explanation of the protean phenomena of puerperal fever itself. Steurer, formerly *interne* at the Bellevue Hospital, where he witnessed the epidemic which prevailed in that institution in the year 1874, afterwards made, under the guidance of Prof. Von Recklinghausen, a special investigation of the pathological changes in a similar

epidemic which occurred in Strasbourg. From a written communication received by me from Dr. Steurer, many of the following facts concerning the pathogeny of the disease have been derived. These facts, I may add, are fully supported by the investigations of others, and form a most valuable contribution to our knowledge of puerperal fever.

Steurer's cases all presented diphtheritic patches about the vulva, or upon the mucous membrane of the vagina and uterus. These patches were always associated with a loss of substance, and were composed of disintegrated fibrin, white and red blood-corpuscles, and colonies of round bacteria in great abundance. From the patches, the bacteria could be traced between the muscular fibres, and deep down into the canalicular spaces of the connective tissue, where their presence gave rise to cellulitis. From the canalicular spaces they entered the lymphatics, with resulting lymphangitis. In many cases the lymphatics could be traced along the broad ligaments to the ovaries (puerperal ovaritis), and into the subperitoneal tissue of the lumbar region. By perforation of the walls of the lymphatics which directly underlie the peritoneum, they made their way into the peritoneal cavity and excited pyæmic peritonitis, an affection which differs from traumatic peritonitis, and for which the claim has been set up that it is peculiar to puerperal fever. The wide stomata upon the abdominal surface of the diaphragm allowed the facile entrance of the organisms into its lymphatics. Waldeyer found in diaphragmitis the lymphatics of the diaphragm filled with bacteria. And thus following the lymphatic system, if we only admit that the round bacteria are the carriers of sepsis, a fact which hardly admits of dispute, the frequency, in severe types of puerperal fever, of inflammations of the serous membranes—of the peritoneum, the pleuræ, the pericardium, and the joints—finds an easy explanation. We can understand, too, how it is not always altogether accident which determines in different cases the precise serous membranes which are affected.

The ductus thoracicus is the principal channel through which the poison enters the blood. Bacteria are not usually found in the blood during life. A few hours after death they swarm in that fluid. Possibly the rapidity of the blood-currents during life does not favor the multiplication of bacteria. That the bacteria do, however, enter the general circulation during life, is incontestable. Steurer writes, "As the kidneys are the great filters of the human system, I never neglected to examine them, and almost invariably found the glomeruli and arterioli filled with micrococci (round bacteria)." This is in correspondence with what occurs in other septic diseases, and accounts for the albuminuria and interstitial nephritis which often supervene in the advanced stages. We have seen already that, in consequence of septic poisoning, the white blood-globules have a tendency to adhere to the walls of the vessels. This leads to stases in the capillaries, to congestion of the deep-seated organs, and to an increase of blood in the large veins of the trunk. Finally death takes place from apnœa, partly from the inability of the blood-corpuscles to carry oxygen to the tissues, and partly from paralysis of the respiratory nerve centres.[1] Sometimes the bacteria pass directly into the veins, where they give rise to phlebitis. Prof. Von Recklinghausen recognizes three ways in which this may take place: (1) Through a thrombus; and here let me call to mind that it is very common in

[1] Vide Schüller. Exp. Beiträge zur Studium der septischen Infection. Deutsche Zeitschrift für Chirurgie, Bd. vi. Heft. 1 und 2, S. 149 u. ff.

uterine phlebitis to find the uterus large, and the vessels at the placental site filled with soft thrombi; (2) through direct perforation of the venous walls; (3) by being taken up by white corpuscles and by them conveyed into the vessels in the manner described by Cohnheim.

When the bacteria enter directly into the circulation, they sometimes, in passing through the heart, adhere to the endocardium and the valves, causing exudation, ulceration, and decomposition, and thus give rise to the so-called endocarditis ulcerosa puerperalis.[1] In the cases studied by Waldeyer and Steurer, there were diphtheritic patches, serving as the starting points of the puerperal processes. Whether these so-called diphtheritic patches are identical with those which appear in the throat, is an open question. Morphologically, they are so, but, in hospitals, epidemics of puerperal diphtheritis are not associated with throat diphtheritis.

To avoid misapprehension, let me distinctly state that diphtheritic patches are not necessary to the infectious form of puerperal fever. They indicate an unwholesome atmospheric condition, and are somewhat rare outside of public institutions. Orth and Heiberg noticed the same, general, post-mortem changes in those cases in which the patches were absent, as in those in which they were present. My own observations show that they are rarely developed in the early stages of a hospital epidemic of puerperal fever, nor are they to be found in all cases when such an epidemic is at its height. In some of the lying-in hospitals in Europe, puerperal diphtheritis appears, however, to be endemic.

The question as to the extent to which erysipelas and puerperal fever are cognate diseases, is in a fair way to be solved by recent investigation. Orth took the contents of a vesicle, from an erysipelatous patient, which contained bacteria in great abundance, and employed the same for injections under the skin of rabbits. In this way he succeeded in producing in these animals a species of erysipelas malignum. In the subcutaneous œdema, and affected portions of the skin, he found enormous masses of bacteria, so far exceeding in quantity the amount introduced as to prove an abundant new production.[2] Samuel produced similar results by the injection of ordinary putrid fluids containing round bacteria. An affection resembling simple erysipelas he obtained most frequently by the application of fluid to a wound torn open after the second or third day.[3] Lukowski found that erysipelas could be produced by fluid containing micrococci even when putrefaction did not exist. The contents of erysipelatous vesicles containing no micrococci, excited no morbid manifestations. Where the erysipelatous process was fresh and progressing, micrococci were found in great abundance in the lymphatics and canalicular spaces. Where the process was retrogressive, there were no micrococci to be found, even in cases in which inflammation existed to an intense degree.[4] Virchow's testimony we have already given.

Thus we find in surgical fever, in puerperal fever, in diphtheria, and in erysipelas, the presence of a common element which links them together, and which establishes the relationship which has long been recognized as existing between these various processes. Experiments made by competent men, with care and intelligence, serve continually

[4] Untersuchungen über Erysipel.; Virchow's Archiv, Bd. lx. S. 430.

to increase the probability that the bacteria are no chance products, but that they have a vital connection with the diseases designated. Whether these organisms are identical in the different infectious diseases in which they have been recognized, is another question. Billroth complains of the monotonous appearance of always the same forms.[1] When we bear in mind, however, that our best instruments fail to enable us to distinguish the ovum which is to produce a mouse from one that will produce a tiger, though the ovum is at least one hundred times larger than the micrococcus, the argument loses something of its value. Whether identical or not, they all possess the common property of penetrating the tissues, under favorable conditions, of multiplying, and of producing, by their migrations, local inflammations and general infection.

I cannot refrain, in conclusion, from quoting entire the following statement of Panum, which appears to reconcile certain differences in the definitions of the term septicæmia by different authors:—

"The putrid poison may, during life, enter the blood with or without bacteria, especially from wounds, and occasion all the symptoms of septic poisoning; whereas, however, the *bacterium termo* does not appear to occur in the blood during life. *This simple putrid infection does not appear to be inoculable.* Another, as it appears, distinct, specific, pathogenic fungus, the microsporon septicum of Klebs, developed especially in pus (and blood?), perhaps under the predisposing influence of the putrid poison, when the air (as in overcrowded hospitals) contains the latter, or when it is transferred by inoculation, seems on the other hand during life to increase in the blood and tissues, and, in part perhaps, by production of a special poison, in part, perhaps, in a more mechanical way, by penetration, and, under circumstances by its irritative action on the tissues, excites inflammation, purulence, and fever."[2]

Causes of Puerperal Fever.

The Atmosphere.—The effect of a poisoned state of the atmosphere is best observed in the so-called nosocomial malaria of hospitals. At Bellevue I have had frequent occasion to witness febrile outbreaks among the patients in the lying-in service, which were instantaneously arrested by closing the tainted ward and transferring the inmates to a healthy locality. As at these times the nurses, the bedding, and the utensils, remained unchanged, it is fair to assume that the previous, unhealthy condition was not due to the transfer of a poison from patient to patient by the attendants, but to something residing in the air of the vacated apartment. In the inquiry as to the production of this condition, it can be assumed that it is not caused by aggregation alone. The medical wards of Bellevue, always crowded, have been in time of need safe receptacles for lying-in patients. It certainly is not due to the presence in excess of what are generally regarded as the ordinary constituents of the atmosphere. We must, therefore, look for some additional element capable of unfavorably affecting the economy. When the disturbance produced by nosocomial malaria is not arrested by change of locality, and the golden moment is allowed to slip by, the secretions of the patients affected become inoculable. Under such circumstances the epidemic spreads rapidly, and assumes continuously a more and more severe type.

[1] Untersuchungen über die Coccobacteria septica, S. 3.
[2] Das putride Gift., etc., Virchow's Archiv, Band lx. S. 349. I have translated literally. The meaning of the sentences, in spite of the involved construction, is sufficiently clear.

If, during such an epidemic, the external genitals be carefully watched, diphtheritic patches may now and then be observed. At first these patches may not be of any special clinical importance. It is possible that they may rapidly clear off, and thus come to be regarded as of little consequence. When, at length, the epidemic has assumed a pestilential form, these patches, which may make their appearance in isolated cases at any time in a hospital, are rarely absent. I have already dwelt upon the composition of these patches, not because I believe that they are essential to puerperal fever, but because their presence tells the tale of what it is in the atmosphere which accomplishes the charnel-house work. Conditions have been present in the air to favor the multiplication of bacteria, and have fitted them to become the active producers of disease. Can we doubt this? First, the epidemic was mild. If a patient, however, died, her tissues and secretions were filled with bacteria, as has been described. Then the epidemic became virulent, and the lesions of the generative apparatus, especially of the external organs which were most exposed to the air, became covered with patches which were found to swarm with micrococci. I cannot, under the conditions named, but consider it more in accordance with ordinary scientific reasoning to conclude that the micrococci played an important part in the production of puerperal fever, than that the puerperal fever produced the micrococci.

To be sure, bacteria or their spores are always present in the atmosphere, and it may be fairly asked how patients are ever spared from their perverse industry. The answer is that they are not always equally active for evil. Bucholz found that the same bacteria, developed in Cohn's fluid, offered more resistance to carbolic and salicylic acids than those cultivated in an analogous fluid which he had adopted. Distilled water renders the action of bacteria extremely feeble. In experiments upon animals, the results obtained with septic fluids depend in no ordinary degree upon the age of the fluid, the material from which it is formed, and the conditions under which it is generated. Micrococci multiply in hospitals when organic materials favorable to their growth are present in sufficient quantities. Robin and others have demonstrated the existence of albuminoid matters in water condensed upon vessels containing freezing mixtures, and placed in overcrowded wards of hospitals. When the results of crowding become manifest, these albuminoid matters not only impart a peculiar fetid odor and putrefy with great rapidity, but rapidly impart putrefaction to normal blood and healthy muscle with which they are brought in contact.[1] Micrococci both cause putrefaction, and serve as the carriers of septic virus. Hueter found putrid blood a most favorable fluid for septic experiments. It was noticeable in Bellevue Hospital that febrile outbreaks always arose in, and were usually confined to, the ward in the hospital which, by a bad arrangement, was assigned to patients for the first four or five days following confinement, *i. e.*, during the period of the lochia cruenta. As puerperal fever is rare after the fifth day, this at first sight would seem natural. But if a patient was transferred directly after confinement, during one of these unhealthy periods, to the ward containing the patients who had passed the first five days, but had not completed the ten days, she would escape the fever. It was always the same ward that required to be disinfected. In a communicating apartment all the confinements took place; and at all times, therefore, the conditions were present for loading the atmosphere with

[1] Leçons sur les Humeurs; Paris, 1867, p. 195.

the products of decomposing blood. In the summer months, as long as the windows were open all the time, the patients enjoyed immunity from nosocomial malaria. In the early fall, as soon as it became necessary to close the windows partially on account of the cool nights, it was not uncommon for the more trivial disturbances, such as so-called milk-fever, the hospital pulse, and catarrhal affections of the genitalia, to manifest themselves. Through the months of February, March, and April, the mortality was usually greatest. During the winter months there was, as a rule, crowding of patients, insufficient ventilation, the saturation of the air with albuminoid materials chiefly derived from blood, which, under the furthering influence of the heat requisite to make the wards comfortable, entered readily into decomposition. That the latter winter months should prove the most perilous, is in accordance not only with the theory of continuous accumulation, but with the experimental fact that weeks sometimes elapse before a decomposing substance acquires the highest degree of virulence.

Apart from the nosocomial malaria of hospitals, there is reason to believe in the influence at times of certain general wide-spread atmospheric states which affect the entire community. In the year 1871, the mortality from child-bed in New York was 399; in 1872, 503; in 1873, 431; in 1874, 439, and in 1875, 420. Now the excess in the deaths for 1872 was due wholly to an increase in the cases of metria, those from ordinary accidents remaining nearly the same as in the preceding years. The disease certainly did not extend into the city from the hospitals serving as foci, for the mortality that year at Bellevue Hospital was hardly more than half the usual average. There was no especial mortality that year from either diphtheria, erysipelas, or scarlatina, but the aggregate mortality was the largest known in the history of the city. There are no positive data connecting the civil deaths from puerperal fever in 1872 with parasiticism, but the prevalence of epizootics, of epidemic catarrhal affections, of peculiarly fatal forms of pneumonia, and other diseases which are now attributed to the presence of minute organisms in the atmosphere, renders such a source highly probable.

It is proper to say here that, though the argument is very strong in favor of regarding the genitalia of puerperal women as the exclusive point of entry into the system of infectious materials, it seems impossible at the present time to make all the facts coincide with such a theory. I have the records of a number of cases occurring during an epidemic of puerperal fever, in which patients were either attacked with fever previous to parturition, or in whose cases the unusual length of labor, the frequency of post-partum hemorrhage, and the imperfect contraction of the uterus, immediately after confinement, were signs of some abnormal influence exercised upon the economy at an early period of labor, previous to the existence of traumatism. That deleterious materials may find other channels for entering the system than a wounded surface, is evidenced by the cachectic condition not unfrequently produced in physicians by too assiduous attendance in dissecting-rooms and places in which post-mortem examinations are conducted. One severe and rapidly fatal case of puerperal fever, which occurred in Bellevue Hospital, I find it impossible to attribute to any other cause than that the woman, for five months previous to her confinement, served as a helper in a lying-in ward. The post-mortem examination disclosed no special local lesions, but her symptoms were those of intense septicæmia. It does not yet seem quite time to give up the idea that, under exceptional circum-

stances, the respiratory, and probably the digestive, tracts, may allow the passage of materials of a septic character.

Inoculation.—Another and frequent source of puerperal fever is by direct inoculation. Any material of a septic character, introduced into the genital passages of a woman during or after confinement, may produce a general infection of the system. But the point upon which I wish especially to dwell is that it is possible to trace epidemics of puerperal fever directly to carrying puerperal poison from patient to patient, through the medium of attendants. In such cases, changes in wards and the most rigid sanitary precautions avail but little, as long as the affected *personnel* is continued in charge. Unless this fact is fully recognized, all the cleverest devices in hospital construction will fail to prevent the occurrence of disasters. In epidemics this source of danger is especially to be guarded against, as septic poison is increased in intensity by successive inoculations. Davaine[1] showed that when a number of animals were poisoned, the one from the other, while from ten to fifteen drops of putrid blood were required to produce death in the first animal, one ten-trillionth part of a drop was sufficient in the twenty-fifth animal of the series, and in puerperal fever epidemics a similar augmentation in the deadliness of the poisons generated by patients is observed.

The nurses in hospitals and in private practice are usually the carriers of contagion. In studying the records of New York City for nine years, I find, however, that the occurrence of two deaths from puerperal disease, following one another so closely as to lead to the suspicion of inoculation, occurred to thirty physicians; a sequence of three cases occurred in the practice of three physicians; one physician lost three cases, and afterwards two, in succession; one physician had once two deaths, once three deaths, and twice four deaths following one another; finally, a physician reported once a loss of two cases near together, then of six patients in six months, and then of six patients in six weeks. Thus in the practice of more than 1200 physicians, in nine years, I find, excluding cases occurring in hospitals, that the experience of thirty-six only lends color to the idea that puerperal fever is due to criminal neglect on the part of the medical profession. Undoubtedly in many of these cases, too, the responsibility is only apparent, as when a practitioner has, for example, had the misfortune to lose in one week a woman from puerperal convulsions, and another in the following week from placental hemorrhage. Singularly enough, not one of the sequences mentioned occurred in the practice of a physician connected with a lying-in hospital. In face of the charge that the physicians holding obstetrical appointments in public institutions are active disseminators of puerperal fever through populous communities, I find that the total loss from all puerperal causes occurring in the private practice of ten physicians intimately associated with such institutions, numbered, during the nine years, but twenty-one cases. Of these, thirteen were the result of ordinary accidents, and only eight cases of metria proper, of which one was developed before the physician was called in attendance; whereas a single physician, holding no hospital appointment, lost during the same time twenty-seven cases, of which twenty-one were cases of metria.

I have been interested in endeavoring to ascertain how far experience corresponds with Semelweiss's theory that puerperal fever owes its origin to poisonous materials obtained from dissecting-rooms, and introduced into

[1] Report before the Académie de Médecine, Sept. 17, 1872.

the genital canal by the hands of physicians attending cases of labor. With this view I have made personal application to a number of gentlemen who have engaged in midwifery practice while performing the functions of demonstrators of anatomy in our medical schools. Dr. H. B. Sands, of the College of Physicians and Surgeons, reports that in the five years during which he held the office of demonstrator, he attended about sixty cases of labor. All did well. He lost his first patient, from child-bed, a short time after he had resigned his position in the dissecting-room. Dr. J. W. Wright, the present Professor of Obstetrics in the Medical Department of the New York University, who held for one year the position of Demonstrator in the Woman's College, writes me that "during the year, I attended one hundred and four cases, including twenty-two forceps cases, two of craniotomy, two of podalic version, and four of breech presentation. Of this number I lost two cases, one from phlegmasia dolens complicating uræmia, from both of which troubles the patient had suffered during her previous labor, and one from double pneumonia, the result of unusual exposure following confinement. Out of these one hundred and four cases, I can recall but three or four cases of metritis, and those of a mild character; I have never thought they had any special connection with my duties in the dissecting-room. I may add that for ten years I have attended a pretty large number of confinements each year, and that during the whole of this time I have been in the habit of making autopsies as occasion has offered, and of handling and examining pathological specimens both in and out of the dissecting-room, notwithstanding which, my death record among this class of cases has been unusually low." Dr. Samuel B. Ward, formerly Demonstrator at the Woman's College, at present Professor of Surgery in the Medical School at Albany, writes: "While I was daily in the dissecting-room, during the winter sessions of the school from 1868 to 1872, I attended thirty-two confinements of which I have notes. All of the patients recovered, nor did any of them suffer from any complication that could be traced to infection." It is familiarly known that after Semelweiss had introduced the practice, among the physicians attending patients at the large lying-in hospital in Vienna, of washing the hands in a solution of chloride of lime, there was a great diminution in the mortality which prevailed, notwithstanding which, G. Braun reports, however, that in 1857, in the month of July, in two hundred and forty-five deliveries there were seventeen deaths. The following month, Prof. Klein gave orders to suspend the use of disinfectants. By chance, in August there were only six deaths out of two hundred and fifty confinements, and in September, of two hundred and seventy-five patients, none died. From 1857 to 1860, the mortality was slight, though disinfectants were not used, while during the three following years, in spite of the systematic and persistent employment of these agents, the death-rate once more assumed formidable proportions.[1]

Of course I do not wish to underrate the importance of Semelweiss's labors. There is no question but that it is a perilous experiment to pass from the dissecting-room to a patient in labor, without employing rigorous measures to disinfect the hands and all parts of the person brought into contact with the dead body. But it is well to call attention to the fact that puerperal fever is not due to any single, simple cause, nor is to

[1] Rückblicke auf die Gesundheits Verhältnisse unter den Wöchnerinnen, u. s. w., S. 32, 33.

be effectually guarded against by a single precaution; and again that cadaveric poison does not of necessity exist in every cadaver examined. Haussmann found that injections into the vagina of gravid rabbits, in the latter half of pregnancy, of serum from the corpse of a person not dying of septicæmia, produced no fatal results, while rapid death resulted from injections, under the same conditions, of pus from the abdomen of a woman dying from puerperal infectious disease.[1]

TABLE II.—*Deaths occurring in New York, between the years* 1867 *and* 1875, *inclusive, from metria, excluding other causes, which proved fatal during the puerperal period.*

Season of Year.—I have in a special table (Table II.) classified all the deaths from metria in New York, during nine years, according to the months in which they occurred, and from this it appears that more than twice as many deaths took place between the six months from December to May inclusive, as between the six months from June to November inclusive. The greatest mortality occurred in February and March, amounting to 499 cases, or rather more than one-fourth of the entire number. The smallest death-rate occurred in September and October, in which months but 150 deaths, or one-thirteenth of the entire number, took place.

[1] The twelfth ward includes Ward's Island Hospital and the Colored Home, which furnished together 102 deaths; deducting these the ratio would be 1 : 99.
[2] The nineteenth ward contains the Nursery and Child's Hospital and the Charity Hospital, which furnished together 83 deaths; deducting these the ratio would become 1 : 82.
[3] Includes 189 cases from Bellevue Hospital, deducting which the ratio would become 1 : 85.
[4] The number of births in each ward is roughly estimated by assuming the population of 1870 to be the average of the nine years, and then allowing 33 births to the thousand. This method makes no pretence to accuracy, but it is not likely that exact returns would materially alter the relative proportions given. It furnishes a total of 279,000, or 5000 less than that obtained by assuming an annual increase of 15,000 to the entire population of the city.

Influence of Locality.—I have likewise prepared a table showing the number of deaths from puerperal causes occurring in each year in the several wards into which the city is divided, and the ratio of deaths to

the estimated number of births in each ward. The average ratio is, as has been already stated, about 1 to 85. In the 9th Ward, however, it was 1 to 188; in the 11th Ward, 1 to 163.5; and in the 15th Ward, 1 to 126. These wards make the most favorable showing in the city. By reference to the map, they are all found to occupy the same territorial zone. In the 17th Ward, situated between the 11th and 15th Wards, the ratio of deaths to births, it is true, was 1 to 79; but the 17th Ward is the most densely populated section of the city. As neither the 9th nor the 11th Wards are otherwise especially favored, both containing a large and crowded tenement-house population, it is hard to understand their relative immunity from deaths due to puerperal diseases, unless upon the assumption that local causes, probably superior drainage, render them exceptionally free from endemic sources of disease.

TABLE IV.—*Deaths from puerperal causes in the* 18*th*, 19*th*, *and* 21*st wards, with the relative proportion of deaths, not occurring in Hospitals, among the population east and west of Third Avenue.*

Year.	Total.	Died in hospital.	Deaths upon the west side of Third Avenue.	Deaths upon the east side of Third Avenue.	Relative proportion of deaths on west and east side, expressed in percentages.

Aggregate . .	986	277	99	610	16.2 "

Social State.—I have, too, sought to ascertain whether the wealthy and well-to-do classes enjoy special immunities from puerperal disease. The district bounded by Fourth and Sixth Avenues, and Twelfth and Fifty-ninth Streets, contains the great proportion of those who make up the privileged classes. In this portion of the city, the proportion of deaths from puerperal causes to the deaths from the same sources throughout the city, is as 1 to 43. The precise population of the district I cannot obtain, but it is safe to say that it contains at least one-thirtieth of the entire population of the city.

The eighteenth, nineteenth, and twenty-first wards, included between Sixth Avenue and the East River, and extending from Fourteenth to Eighty-sixth Streets, contain in a marked degree the two extremes of wealth and poverty. Third Avenue separates the territory into two equal parts, and forms a fair dividing line between the upper and the lower social strata. The population upon the west side of Third Avenue is, it is true, less than that upon the east side,[1] possibly not more than half as great, but the mortality of nine years from puerperal causes was in this favored region less than one-sixth, even after deducting

[1] I am informed by politicians that the vote in the ward mentioned is about 50 per cent. larger on the east side of Third Avenue.

deaths occurring in hospitals, which for the most part lie upon the east side. In 1872, the fatal year, the proportion was one to twelve.

TABLE V.—*Deaths from scarlatina, diphtheria, and erysipelas, and from all causes, by quarters, compared with deaths from metria, for the nine years ending December* 31, 1875.

Relations to Zymotic Diseases.—I prepared, some time ago, tables to answer the inquiry as to whether there was any relation between the frequency of cases of scarlatina, diphtheria, and erysipelas, and those from metria proper. Previous to their publication, however, I was anticipated in my deductions by a paper upon the same subject by Dr. Matthews Duncan.[1] I therefore simply submit the tables with the comment that

[1] On the alleged Occasional Epidemic Prevalence of Puerperal Pyæmia, or Puerperal Fever, and Erysipelas; Edinburgh Medical Journal, March, 1876, p. 774.

they show no relation to exist between the statistical frequency of puerperal fever and the zymotic diseases mentioned. The tables do not, however, invalidate any direct testimony which goes to show that, in individual instances, a real connection between puerperal fever and the zymotic diseases may exist.

Prevention of Puerperal Fever.

Of the 3342 deaths from puerperal causes, 420 died in hospital, or one-eighth of the entire number. Of the 1947 cases of metria, about 300, or not quite one-sixth, were contributed by the hospitals. Upon such a showing the first impulse would be to cry out loudly for the suppression of maternities. But a wiser policy suggests the inquiry whether the large mortality in hospitals is an evil necessity. To this the answer is "No." It is possible, in the present state of our scientific knowledge, to so control the conditions that favor the generation of puerperal diseases in large hospitals, as to make them safe asylums for the needy.

Thus in the Charity Hospital, Dr. Kitching reports the number of confinements between July 1, 1874, and May 1, 1876, at 1149; of which 20 ended in death, or 1 in 57. But only six were cases of metria, or 1 in 191 deliveries, a better record than that afforded by the average of the city at large. In the Nursery and Child's Hospital, there was but one death from metria in 1874, and one in 1875. In 1872, the number of confinements was 205. I regret that a request for the number of confinements in the succeeding years has been refused me. The Marion Street Lying-in Asylum, an excellent institution for married women, reports two deaths from metria in nine years. Dr. Goodell reports that, at the Preston Retreat, in 756 cases of labor there have been but two deaths from septic disease; Winckel,[1] of the Lying-in Institution in Dresden, reported, in 1873, eighteen deaths from metria, or 1.8 per cent., but from the 10th of January to the 7th of July, in 570 deliveries there was but one case of septic disease; in the year 1872 the death-rate exceeded 5 per cent. The reduction in the mortality was no fortuitous circumstance, but was due to rigid measures for the prevention of disease.[2] Stadfeldt reduced the mortality from puerperal fever, in the Maternity Hospital of Copenhagen, from 1 in 37, the proportion between the years 1865 and 1869, to 1 in 87, between the years 1870 and 1874.[3] Dr. Johnston reports in the Rotunda Hospital of Dublin, during seven years, 7860 deliveries (I have excluded the cases of abortion) with 169 deaths, of which 85, or 1 in 91, were from metria.[4]

Prof. J. J. Bischoff reports that in the Maternity of Basel, between the years 1862 and 1867 inclusive, in 514 confinements there were 33 deaths, or in about the proportion of one to sixteen. In 1868, of 75 patients confined, there died three, or one in twenty-five. In 1869, of 86 patients confined, seven died, or one in twelve. In 1870 effective measures of prevention were introduced, and, that year, in 80 confinements there were no deaths.[5] In 1871, two out of 124 patients died, or one in sixty-two. In 1872, in 153 confinements there were four deaths, a proportion of one

[1] On the Means employed at the Preston Retreat for the Prevention and Treatment of Puerperal Diseases, p. 13.

[5] J. J. Bischoff, Zur Prophylaxis des puerperal Fiebers; Basel, 1876, S. 12, 13.

to nearly forty. The next year, 1873, strict measures were again put in force, and in 184 labors there were two deaths, or one in ninety-two. In 1874, in 214 labors there were three deaths, one to seventy-one, but one of the patients entered the hospital with endocarditis, of which affection she died. In 1875, in 204 confinements there were two deaths, one from hemorrhage, and one from pyelitis which existed at the time the patient entered the hospital.

Surely these figures do not support the idea that it is better for a woman to be confined in a street gutter than to enter the portals of a lying-in asylum. Dr. Goodell's experience shows that a hospital for respectable married women may be so conducted that its inmates may enjoy absolutely a greater degree of safety than do women in their homes, surrounded by all the aids that wealth can command. Equally good results are not to be obtained in hospitals which are open to unfortunates of every class. But there is much misapprehension and confusion of ideas respecting the fate of these women, when no charitable provision is made for them. In Copenhagen, the Maternity Hospital is closed for from six to eight weeks in the summer time. During this period, unmarried, parturient women receive pecuniary assistance from the hospital to enable them to obtain a place in which to be confined. Now Stadfeldt reports a larger mortality among this class than among those delivered in the hospital. Yet they are confined at a favorable season of the year, without any communication with the furniture, the *sage-femmes*, or the physicians of the hospital. As they fortunately receive nothing but money, that can hardly be suspected of communicating contagion. What their fate would be in New York City, perhaps, may be judged from the following facts: Excluding cases confined in hospitals, nearly one-thirtieth of all the deaths and one-twenty-fourth of the cases of metria are reported by four practitioners. Ten practitioners out of 1200 signed the death certificates of one-fifteenth of the women dying from puerperal causes, and one-tenth of the cases of metria. But it is not to be supposed that these deaths were all the result of malpractice and incompetence. The true history of most of them probably was that the doctor was engaged to attend the case of confinement for a small fee, with the understanding that he should make no calls subsequently, unless specially summoned by the friends of the patient. The latter, left to ignorant care, or perhaps without any assistance whatever, and exposed to all the pernicious influences bred by poverty, when illness supervened probably did not call the physician to her aid until the time for help had passed, so that in the end his professional functions were confined to procuring the requisite permit for burial.

Humanity demands that charity should furnish places of refuge in which poor outcasts can receive assistance during the perils of childbearing. If we must then have maternities, we should make them safe, and this can be in great measure accomplished by remembering the twofold source of danger arising from a poisoned atmosphere and direct inoculation. A hospital must be clean, spacious, and well ventilated, or its atmosphere will become charged with decomposing albuminoid substances, and produce nosocomial malaria. But the experience of the Hôpital Cochin,[1] a costly, palace-like structure, with every appliance of art, proves that fresh air alone does not protect patients from the consequences of inoculation. On the other hand, the most rigid sanitary pre-

[1] Billet, Réforme des Maternités, p. 75.

cautions observed by the attendants will not prevent a badly ventilated ward from becoming unhealthy, unless unoccupied wards are kept to which patients can be transferred upon the first admonition of danger. At the Charity Hospital, the service consists of two large wards, occupied for three weeks at a time alternately. Dr. Goodell states that at the Preston Retreat the wards are used invariably in rotation. In connection with the Maternity at Copenhagen, there are a number of small supplementary hospitals scattered through the city, which serve as safety-valves for the central institution. Artificial methods of ventilation render the task of keeping the wards healthy, comparatively easy. They do not need, however, to be complicated and expensive. The good repute of the Rotunda Hospital, it seems to me, is in large measure due to the natural ventilation afforded by open fireplaces.

The testimony is very general to the advantages of frequently washing the wards with carbolic acid. At the Charity Hospital, in addition, the wards are fumigated three times a week by burning a mixture of carbolic acid, chloride of lime, and sulphur. During parturition, Stadfeldt exposes the woman to a fine spray of carbolic acid. If, after confinement, vaginal washes of carbolic acid should be used, every woman should be supplied with her own nozzle, which can be made of glass tubing, and attached in turn to the irrigator. When not in use, these should be kept in solutions of carbolic acid.

A liberal supply of metallic catheters should be always kept on hand and, when not in use, placed in a disinfectant fluid. Sponges, in a hospital, are an abomination. Oakum, lint, or old cloths should be employed to receive the discharges, and, when removed, should be placed at once in a vessel containing disinfectants, and then, instead of going into the washtub, should be burned. As regards all prophylactic measures, cheapness is not to be consulted.

As puerperal patients require much attention, lying-in wards should possess a sufficiency of attendants, best, perhaps, by making them training schools for nurses. Nurses should be intelligent enough not only to comprehend their duties, but their responsibility. Physicians should wash their hands with disinfectants before and after making examinations, and nurses should do the same whenever their hands are brought into contact with vaginal secretions. D'Espine has shown that the lochia of the third day of a healthy patient will poison a rabbit.[1] A nurse employed in the puerperal wards ought not to have access to cases of labor. A patient attacked with fever should be immediately removed to another part of the building, and the nurse in attendance should go with her. Special wards for the recently confined should never be established. As enforcement of details is essential to success, a lying-in hospital should have a resident medical head with plenary power to enforce the most rigorous discipline. The adoption of Lister's principles in maternity hospitals has, when carried out with the requisite discipline, served to dissipate the well-founded objections to their existence. It makes no difference whether they are old hospitals or new, cottages or pavilions. All that is required is space, light, air, intelligent nursing, an active head, and generosity in needed supplies, to keep them as free from infectious diseases as are the homes of the better classes. I have already shown, in another paper, how, through limited room, ignorant nurses,

[1] Contributions à l'Étude de la Septicémie Puerpérale, p. 18.

lax discipline, and niggardly management, an epidemic, costly in life, could be generated.

So far from tearing down the maternity hospitals now in existence, new maternities of small size, for married women, modelled after the Preston Retreat, are urgently called for to meet the present waste of life among the very poor. I cannot but hope that such institutions, intelligently constructed, ordered, and maintained, may yet be the outcome of private charity. A small maternity has the advantage over a large one that, when a dangerous element is introduced, repressive measures can be more rapidly and effectively carried into execution. I have already taken up so much time that I will not dwell upon the duties of the physician toward his private patients: how he should avoid conveying to them zymotic diseases, or septic poisons; how he should understand that the proper management of labor involves a normal puerperal state; how he should guard lest the antecedents of his patients should unfavorably affect the period of parturition and child-bed. I have only to add that, among the wealthy and refined, there is an annual sacrifice of lovely women, due, not to want of skill or care, not to infection, but to the fact that the enervating influences of civilization and the pressure of social life, have apparently unfitted them for offering effective resistance to any form of traumatism. Dr. E. H. Clarke's little work entitled "Sex in Education," strikes the key note of a subject requiring on the part of obstetricians the profoundest consideration.

In closing this paper, I beg to offer the following conclusions:—

I. There is no specific, puerperal fever, and, as long as, when the term is limited, each physician uses it in some sense personal to himself, it is best to employ it as a general term for all the febrile affections peculiar to the puerperal state.

II. Puerperal fever, the term being used as above, may be either a non-infectious or an infectious disease.

III. The non-infectious form is due to traumatic inflammations of a simple character, to old peritoneal adhesions, to moral causes, and to the vulnerability of the patient.

IV. The infectious form, on the other hand, is a septic disease, intimately associated with the existence in the tissues of minute organisms which form the connecting link between puerperal fever and erysipelas and diphtheria.

V. Its causes are certain atmospheric conditions (nosocomial malaria of hospitals), and infection from septic materials. It prevails most in certain winter months, and finds its victims chiefly among the very poor.

VI. Prevention is best accomplished in hospitals by the adoption of Lister's principles.[1] Maternity hospitals are no longer necessarily foci

[1] The following regulations, enforced by Bischoff, in Basel, will serve as an example:—Removal from the genitalia, after confinement, of *débris* capable of undergoing putrefaction. Protection of the wounded surfaces from all air not impregnated with carbolic acid. Hands of attendants, and all instruments used in labor, to be disinfected with carbolic acid. A full bath to be given upon the advent of labor, and the vagina to be washed out with a two per cent. solution of carbolic acid. In cases of premature rupture of membranes, of protracted labor, artificially induced premature labor, and of dead fœtus, a repetition of the injection every two hours. Hands and instruments to be lubricated when necessary with a ten per cent. preparation of carbolized glycerine. In cases of version, of artificial removal of the placenta, of putrid fœtus, of post-partum hemorrhage with relaxation of the uterus, employment of intra-uterine injections of two to three per cent. solutions of carbolic acid. After the end of labor, the external genitalia to be inspected, and a ten per cent.

of disease. Small maternities, if well managed, meet a need among the very poor, and their establishment by the charitable should be encouraged. In private practice the physician should never, and need never, be the carrier of contagion. The antecedents of nurses should be investigated. Auto-infection should be very rare in cases properly managed during the period of labor.

VII. The question of personal responsibility cannot be too strongly impressed upon the medical profession.

Discussion on Dr. Lusk's Paper.

After the reading of the preceding paper, Dr. H. P. Yeomans, of Mount Forest, Ontario, Canada, said:—With regard to Dr. Lusk's statement that bacteria in puerperal fever cause endocarditis, I would say that the presence of lactic acid in the blood may produce precisely the same cardiac conditions, and that when injected into the veins of animals, it has developed endocarditis, and caused deposits of fibrin on the valves. Now it is a significant fact that, in cases of puerperal fever, lactic acid is one of the morbid constituents of the blood. In such cases it is not necessary, therefore, to invoke the presence of bacteria as the cause of the endocarditis.

Dr. William Goodell, of Philadelphia, said:—I have listened with much pleasure to the admirable paper just read. There are points in it on which I should like to dwell; but, as the time for discussion is very limited, I shall confine my remarks to the prevention of puerperal disorders. I contend that no statistics are trustworthy, excepting those of hospitals and of other public institutions, for physicians very naturally shrink from reporting their fatal cases of puerperal fever as such. In evidence of this, I may adduce the fact that at one time I was cognizant of fourteen deaths in two weeks from puerperal fever. Yet the weekly mortuary returns of the Board of Health gave for that time but twelve deaths *in the whole city* from that disease. With regard to the prevention of fever in the inmates of the lying-in institution of which I am in charge, I am governed by four golden rules: *Cleanliness*, *Ventilation*, *Rotation*, and *Isolation*. And I am the more satisfied with them since, among 1021 hospital patients who have passed under my care, I have not had a single case of phlegmasia dolens, and but one of pelvic abscess, while I have lost only three from fever. Each one of these rules is a generic term embracing many specifications, but since the first three explain themselves, I shall dwell on the last only. By isolation I mean the imitation of the home-environment—in other words, the putting a hospital patient in a condition as like as possible to that which she would have at home. While this ideal cannot be wholly reached in a hospital, yet it should be approached as closely as possible. If the same sponge, the same chamber-pot, or the same syringe, be used by several patients, this law of home-environment is violated; for every woman delivered at home has her own sponge, her own syringe, and her own vessel. Hence in place of sponges I use finely picked oakum, with which every woman—and not the nurse—washes her own person. Hence every bed is provided with its own vessel, and hence every woman's person is sweetened,

carbolized oil to be applied to all lesions. Rupture of the perineum to be closed with carbolized silk or catgut sutures. The parts to be washed clean, and picked lint soaked in carbolized oil (ten per cent.) to be laid upon the vulva. Vaginal injections of a two per cent. solution of carbolic acid to be used twice a day—or, in cases of difficult labor, putrid fœtus, or retained portions of ovum, to be repeated every two hours. In cases of retained portions of placenta, hindering the contraction of the uterus, intra-uterine injections of a two or three per cent. solution of carbolic acid in water twice a day. The nurse to wash at each visit the genitalia and inner surface of the thighs, with a lukewarm solution of carbolic acid. I have already given the results of this treatment.

not by detergent vaginal or intra-uterine injections, but by the upright position, by making her get out of bed and slip into a chair several times a day. Since the same ward holds, and the same nurse attends, a number of women at the same time, this is a flagrant violation of the law of home-environment, but one which cannot be avoided in hospital practice. As a make-weight, however, I put but few women in the same ward, and make the nurse use a nail-brush, take frequent baths, and wear such clothing as can be washed. As soon as the women are out of bed for good, the nurse is relieved from duty; she takes a carbolized soap-bath, and goes into a clean ward, which has lain fallow for some two weeks or more, and usually gets a week of rest before a new batch of patients falls to her care. I myself always wash my hands with carbolized soap, before making an examination, and, to make assurance doubly sure, I keep an obstetric and a gynæcological hand. With my left hand I make all my office and dispensary vaginal examinations; my right hand I reserve as much as possible for obstetric work. Since moist heat forms the condition under which poison-germs best germinate, after a ward is once occupied, the floor should not be washed. An accidental stain may be wiped up, but nothing more. I have been led to this practice from observing that the cleanest ward-floor, when drying, emits a bad smell, and from finding, some hours after such a floor-washing, that the body temperature of my patients often shows a sharp curve-peak. From the cloud of epidermic scales, and of other human and consequently septic *débris*, raised by the broom, I am also opposed to sweeping a ward, and especially while any patient is in it who has not yet got her milk—that is to say, whose labor-lesions have not yet become protected by a covering of granulations. But, since such a mode of enforcing cleanliness, although a wide departure from our ideal of the home-environment, cannot be well dispensed with, I would suggest the plan devised by my friend, Dr. Addinell Hewson, viz., to strew the sawdust of some terebinthinate wood, such as cedar or pitch-pine, over the floor of the ward before it is swept. The sawdust of any ordinary wood would do, if sprinkled with turpentine, which, while being antiseptic, would give the needful amount of dampness without moistening the floors. Since fatty degeneration of the heart as well as of the other viscera is one of the most common lesions of child-bed fever, to avert this tendency large doses should be given of such antiseptics and antipyretics as quinia and alcohol, combined with opium enough to allay all pain. And such a heart-tonic as digitalis should be given instead of a pure depressant like veratrum viride.

Dr. W. H. Byford, of Chicago, said:—I believe with Dr. Lusk that puerperal fever is produced by many different causes, and assumes many different forms. Sometimes it originates under isolated conditions, and is autogenetic, resulting then from various intrinsic causes, such as decomposition of blood clots, or of retained membranes, etc. In others it has a zymotic origin from various extrinsic causes, which prove at times morbific, owing to the peculiar state of the patient. Frequently cases of puerperal fever result from overcrowding in hospitals; at least they are always more prevalent in close buildings where there is no good ventilation. The disease ought not to be called epidemic; it is rather endemic. But there is another class of cases which differs from these, especially in miasmatic sections. Some years since I witnessed an epidemic of "black tongue" which occurred in Indiana. During the height of the disease, which lasted two months, every case perished and every lying-in woman in that neighborhood died of puerperal fever; but as the epidemic subsided, the virulence of the fever grew less, and some cases began to recover. When, finally, the "black tongue" disappeared, puerperal fever vanished with it, and the younger doctors then thought that they had discovered the cause of the latter disease. I believe puerperal fever to be contagious under certain circumstances, but think that it cannot be carried by the physician after he has washed himself with carbolic acid.

Dr. John L. Atlee, of Lancaster, said:—I had attended a thousand cases

of labor without seeing puerperal fever, and from this good luck had argued that there was no necessity for more than ordinary cleanliness on the part of the physician. But once I had a case of phlegmonous erysipelas, which I dressed, and then, during the succeeding afternoon and night, attended three cases of easy delivery. The next morning I left them in charge of a friend, and went to Baltimore as a delegate to the American Medical Association. On my return I found my friend waiting for me at the station, to take me to see these women, all of whom had puerperal fever. I found one already dead, and the other two hopelessly ill. Under the teachings of Hodge and Meigs, it would then have been considered heresy to say that puerperal fever was communicable, and yet I carried the disease, having used no special disinfectant, and I believe that I was the innocent cause of the death of those three ladies. I therefore urge that the profession should use extraordinary measures against personal infection and the carrying of this disease.

Dr. J. P. WHITE, of Buffalo, said:—Puerperal fever was said years ago not to be communicable, but most of us have changed our minds upon this point. We may call it infectious or contagious as we will, but it has spread about neighborhoods. I know of cases in which it has been carried, and I know that it is communicable. The opposing opinions of Dr. Hodge, Dr. Meigs, and others, have been overturned, and there is now no doubt that puerperal fever is eminently contagious. No man has a right to go directly from a case of puerperal fever, and attend another patient in labor. I know of no disinfectant that will make it safe to attend a case of labor after one of puerperal fever. In the treatment of this disease, I place much reliance upon opium, for which there is great tolerance in puerperal fever. I have given as much as one grain of morphia every hour for forty-eight consecutive hours, and have been rewarded for my boldness by the recovery of my patient.

Dr. E. H. TRENHOLME, of Montreal, said:—I have given from a grain to a grain and a third of morphia, every hour, with positive benefit; and I have never lost a patient from puerperal fever, although I have met with five cases.

Dr. J. C. HUBBARD, of Ashtabula, Ohio, said:—I should like to test the sense of the Section as to whether, in cases of puerperal fever, the child should be allowed to remain in bed with the mother or not. Most physicians allow the child to remain as long as it can get a drop of milk.

Dr. GEORGE W. MEARS, of Indianapolis, said:—I consider puerperal fever more infectious than contagious, in the strict sense of those terms. I knew a physician once to lose seven cases of labor from this cause within two weeks (every case of the kind which he attended), notwithstanding that he had used all necessary precautions, such as the free application of disinfectants, change of clothes, etc. They were obviously all instances of personal transmission, no other physician in the city having had a case of the kind to treat. A few weeks' absence from home served to free him from the infecting influence, no other instance of the disease having subsequently occurred in his practice. I believe it also possible that the fever arising from other causes than that of erysipelas may be conveyed, but not as readily, by the attendant on labor. According to my observation, when the infection arises from erysipelas the child develops erysipelas and the mother peritonitis.

Dr. ALEXANDER R. SIMPSON, of Edinburgh, said:—The chapters in our text-books, instead of being headed "Puerperal Fever," as they are, should be entitled, "On the Fevers of the Puerperal State," not specially referring to puerperal fever as an entity. The puerperal woman is liable to ordinary diseases, but in her they assume peculiar features, and are so marked as to give rise to the idea of a special disease, called puerperal fever. I believe that often these fevers are merely typhoid fevers in the puerperal woman. In some cases the development is due to the poison of scarlatina; but both typhoid and scarlet fever are diseases which are as natural to the puerperal woman as to the non-puerperal. I do not know whether such tables have been drawn up, but I should like to see statistics of the results of wounds re-

ceived in battle, as to the difference in the ratio of recovery of those wounded early in the day, when they are fresh, and those wounded later. Such data would apply to cases of puerperal women; whether the women are fresh from a short labor, or exhausted by a long and tedious one. With our present knowledge of the subject, it matters little, as far as treatment is concerned, whether the poison be chemical or animal. To meet the difficulty of personal infection, we should be careful not to carry the poison about in our daily rounds. Most of the germ destroyers are acids, as carbolic, sulphurous, and salicylic acids, but, as a disinfectant, I would call attention to one which can be found in every household, and that is common vinegar; I have, on many occasions, found it extremely efficacious. After extraordinary exposure, the clothing should be fumigated with sulphurous acid.

Dr. Lusk, in reply, said:—I beg to thank the Section for the attention which has been given to my paper, and for the discussion which has followed. In reply to Dr. Yeomans, I would say that it is true that the presence of lactic acid in the blood causes endocarditis, but that I confined my remarks to a single form of endocarditis, of which the great characteristic is the presence of masses of bacteria upon the cardiac valves. But the great question is, whether the poison can be destroyed after its inoculation has taken place. I think that it can. I think that the mother ought to be separated, in these cases, from the child, as it is better for both. I use Labarraque's solution to disinfect my hands, and have never carried the disease from hospital to private patients.

ON ELECTROLYSIS, WITH SPECIAL REFERENCE TO THE TREATMENT OF OVARIAN CYSTS.

BY

FREDERICK SEMELEDER, M.D.,

OF VIENNA.

Electricity, the essential nature of which we are unable to explain, reveals itself to us under all the different known forms of motion, both as mechanical power and as molecular movement, whether as light, heat, or chemical action. The phenomena of these are essentially identical; they are correlative, and are constantly being transformed one into another. We can command, to a certain extent, by choosing among the various sources of electricity, and by different arrangements of apparatus, the particular manifestation which we wish to produce; but no form of electricity can be generated which does not display, more or less, all its various qualities. Especially is it impossible to conceive of any electric current acting on a living body without causing chemical action, and perhaps the only way in which electricity can act in the living tissues is through its chemical effects.

Electrolysis is the name given to that application of electricity in which chemical action is principally sought for, and, especially in medicine, when, by the use of either the galvanic or the faradaic current, an attempt is made to dissolve or destroy organic productions, infiltrations, exudations, or distinct tumors. Electrolysis is extensively used for industrial purposes (electrotyping, etectroplating, etc.), but its applications to medicine and surgery are as yet very limited; this branch of electro-therapeutics is still in its infancy, its philosophy is very imperfectly understood, the number of cases in which it has been employed is small, and the data for judging of its value are widely scattered; the time for writing a treatise on medical electro-chemistry has not yet arrived.

The effects of electrical currents on simple, inorganic solutions are easily understood; but it is different when we have to deal with organic and highly complex substances, such as are met with in the living body. An electric current passing through common water decomposes it, setting free oxygen at the positive and hydrogen at the negative pole; with a solution of common salt a similar process goes on, the oxygen formed at the positive pole acting on the salt and decomposing it. In the case of liquids like those found in the living body, containing albumen and azotic combinations, we know, as a general rule, that, at the positive (oxygen) pole, albumen, fibrin, fat-acids, etc., are separated, while at the negative (hydrogen) pole there appear the alkaline and earthy bases, iron, and coloring matters.

If an electric current is passed through a watery solution of albumen, in a short time (say five minutes) a clot will be found at each pole; that at the positive pole is the larger and denser, the wire (copper) becomes green by oxidation, and the whole clot has a slight, greenish tinge; the clot at the negative pole is more cloudy, soft, and diffuse, and of a grayish tinge, while the wire becomes blackened from the development of

sulphuretted hydrogen. The same thing is observed (except that the clots are smaller) when the wires are applied, after the shell is removed, to the soft membrane which covers the white of an egg. The above remarks apply to the constant, galvanic current; although the faradaic current also decomposes water and coagulated albumen, yet the electrolytic properties of any faradaic current, which a living subject can endure, are so insignificant, that its value in this respect may be disregarded.

What has been described as taking place in an albuminous solution, is precisely analogous to that which occurs in the living body, the effects varying somewhat, however, according as both poles are introduced or applied on the surface, or as one or the other is introduced while the other is applied externally; and from a knowledge of these differences may be derived varied indications for the therapeutic use of electricity.

With these introductory remarks, I beg to call the attention of the Section to a new application of electricity in surgery; I mean the electrolytic treatment of ovarian cysts. When, a year ago, I published my first successful cases, a claim of priority was made by two gentlemen, one of whom had indeed reported cures of ovarian cysts, by electricity, as long ago as 1859. But these cases excited no attention at the time, and were so entirely forgotten that in Prof. Schrœder's Essay on Gynæcology, in Ziemssen's Cyclopædia, no earlier cases were referred to than those of Dr. Fieber, published in 1874. All that I claim is the credit of having again brought the method before the profession, and I sincerely hope that it will not require fifty years to elapse before the value of this mode of treatment is acknowledged, as was the case with ovariotomy, the great invention of Dr. McDowell, from whose deserved reputation I would certainly be the last to detract.

But science is constantly progressive, and what was yesterday considered a great triumph, may to-morrow be superseded, and just as legitimately abandoned as it was praised the day before. Hence I do not hesitate to repeat, before this assembly, my assertion, that I hope within a short time to see ovariotomy abandoned, or at least restricted to a very few exceptional cases. My grounds for entertaining this opinion I have recently published at length, and shall not therefore repeat at this time what I have already written; but I will merely say that six cases of ovarian dropsy, which I have treated in this way, have been completely cured in from four weeks' to five months' time, according to the size of the tumor; and that in a case of fibro-cystoma of the womb, under electrical treatment, the liquid contents of the cysts have been absorbed, the fibrous, solid masses remaining nearly unaltered. The ovarian cases were not selected but were taken indiscriminately; the cysts varied in size from that of a cocoanut to that of a pregnant uterus at full term. In one case the tumor was undoubtedly monocystic, with thickish contents; and in another polycystic; in two cases the cyst contents were quite thin; while one was probably a case of dermoid cyst. The ages of the patients varied from eighteen to forty-five years; one was a virgin; one married, but sterile; and four had borne children.

The constant current was employed in all the cases; in one, no needles were introduced, but both electrodes applied to the surface, and yet the contents of the tumor were absorbed. The currents employed were mild ones; no inflammation of importance occurred, and consequently no adhesions were formed; the pain was insignificant, anæsthetics never having been required, and no patient having been confined to bed. Thus far, no relapse has occurred. The method is equally applicable to

single and to multiple cysts; to those with albuminous, with saline, and with fatty contents; to those with and those without adhesions; to those which have and those which have not been previously tapped.

In one of my cases, after the liquid contents had been absorbed, hard, cartilaginous bodies in the cyst remained, apparently unaltered; the cyst walls, in all, underwent contraction, and a solid lump, of the size of a small apple, remained when all the liquid had disappeared. One obvious advantage of this method of treatment over ovariotomy, is that it does not deprive the patient of one of her most important organs. The sittings, in my cases, usually lasted only a few minutes, and were repeated daily—in one case, even during the menstrual period.

The *modus operandi* of this method of treatment is not thoroughly understood. In addition to the decomposition and absorption of the liquid, some change must take place even in those parts of the cyst walls which do not come into direct contact with the electrodes, for the further production of liquid is prevented. Dr. Althaus's theory as to the effect of electricity on tumors containing saline liquids, is that, the salt being decomposed, a caustic alkali is formed, and by setting up a mild inflammatory process increases the vitality of the tissues, and thus leads to the absorption of the fluid.

Before resorting to ovariotomy in any case, the surgeon should at least give electricity a trial; for, even if it fail, the patient will be in no worse condition for the operation, while the risks of the latter more than counter-balance the evil of a little delay.

PARACENTESIS, ASPIRATION, AND TRANSFUSION.

BY

SIMON FITCH, A.M., M.D. Edin.,

OF ST JOHN, NEW BRUNSWICK, CANADA.

Fifty years ago, paracentesis was seldom employed, except in cases of fluid distension of the abdomen, bladder, or scrotum, after other means of relief had failed, and then it was a clumsy and unvalued procedure. The old trocar, having a triangular point and a big head, with a split canula behind it, went in with a jerk, endangering intestine and testicle in tapping for ascites and hydrocele; then the canula, pushed onwards over the big head expanding the segments of its split end, would often catch some bit of the three-cornered aperture, and fail to enter perfectly, or in entering would tear or split up the edges of the aperture, and allow the fluids to leak injuriously into or upon the neighboring tissues, as in the operation for hydrocele, or in puncturing the bladder; and finally, the instrument would leave a jagged, punctured wound, indisposed to heal.

But at the present time paracentesis is called upon both to detect and treat a marvellous variety of diseases, and some of them of great importance, such as hydrothorax, empyema, hydro-pericardium, ascites and purulent deposits in the abdomen, cysts of the broad ligament and of the ovary, intra-pelvic and lumbar abscesses, retention of urine with impermeable urethra, distressing tympanitis, strangulated hernia, hydatids and abscesses of the liver and kidneys, hurtful effusions within or about the hips and other joints, hydrocephalus, and spina-bifida; and the present duties of paracentesis are more critical, in consequence of the sensitive and vital character of the textures and parts in and upon which many of these diseases are situated, such as the lungs, the heart, the abdominal viscera, the pelvic organs, the great joints, the spinal cord, and the brain.

In dealing with such diseases, in such parts, none of the trocars now in use are equal to what is required of them, either for exploration or for treatment.

Paracentesis now, with or without aspiration, with or without injection, is commonly done either with a single tubular trocar having an unguarded point (which is most dangerous to the interior), or the guard is an open canula, to be pushed over the point after it has entered, and of itself only somewhat less dangerous if it gets in, while it is uncertain to enter; and we will do wrong to employ these uncertain and dangerous instruments if an efficient and safe instrument can be had.

The perfect trocar should be: (1) *Easy of insertion*, the puncturing tube entering by a clean incision, and the protecting canula following without the least stretching of the aperture, or possibility of failure; (2) *Harmless when inserted*, so that it shall not injure the interior of the cavity, or adjacent parts; (3) *Safe as a probe or sound*, or artificial finger, for internal exploration; (4) *Adapted to the aspirator* and every form of exhausting apparatus, both attachment and detachment being instantaneous; (5) *Competent to give the freest exit or entrance* to fluids to be dis-

charged or injected; and (6) *Certain to leave an incised wound*, ready to heal. Let us now glance at the growth and present character of the modern trocar, and try to ascertain what should be done towards perfecting it.

In 1850 the improvements seem to have commenced, when Sir James Y. Simpson reduced the large head of the old trocar to the same size as the shaft, so that it should stretch the orifice less, and, as the canula could then be advanced without spreading, he omitted the split in the end, and published his employment of a long and slender trocar of this kind, with an exhausting syringe attached, as a means of diagnosis in various internal enlargements, especially in pelvic tumors, and so initiated the idea which Dieulafoy afterwards developed into his admirable aspirator. The plan of having the canula itself pointed, so as to penetrate independently of the stylet, was first conceived by Fergusson, of London, who in 1853 devised a pen-like tubular needle, for injection of perchloride of iron in the treatment of nævi and aneurisms. In 1858, Dr. Alexander Wood, of Edinburgh, adapted this instrument to the subcutaneous injection of morphia, and a modification of the same instrument is now in universal use. Shortly afterwards, Mr. Spencer Wells enlarged this little tubular trocar, for ovarian tapping, and had the edges of the pointed end made sharp and cutting for one half the circumference of the tube, whereby a semilunar incision is made; and he added, or restored, a shorter sliding canula on the outside, which, upon the puncture being effected by the point of the inner tube, is pushed forward as a guard against its further cutting action.

This instrument, superior in many respects to the old trocar and canula, especially in that the wound made is incised, rather than punctured, has still this grave fault of the old instrument, that the protecting canula is on the *outside*. If the distal orifice of this outer canula be made thin to pass with less resistance through the aperture made by the pointed smaller tube, the open thin end will itself present a cutting edge dangerous to the interior of the cavity and to the contained or adjacent viscera. To lessen the difficulty of getting the outer canula through the aperture, over the inner tube, the distal end is sometimes made obtusely pointed, but this makes it only the more dangerous to the interior, especially in the smaller or aspirator sizes of the instrument. If on the other hand the terminal margin of the outer canula be blunted or made thicker, it will present a ridge or shoulder outside of and behind the entering point of the inner tube, liable to catch and carry before it the sac, or the immediate investment of the cavity, and so fail to properly enter.

Now, this accident may occasion considerable inconvenience, or even be productive of great harm, in cases of simple tapping; as for instance in hydrocele and in retention of urine, where, if the tunica vaginalis or bladder be not very tense, it is oftentimes difficult to get the outer canula in without pushing so hard as to endanger its going in with a jump, and hurting something, so tightly does the punctured membrane cling to the inner tube in advance of the edge of the outer canula; and in empyema, with a thick and tough pleura, so much force is sometimes required to urge the entrance of the outer canula, as to endanger a separation of the pleura from the ribs. And in tapping for the temporary relief of ovarian dropsy, if the outer canula do not follow the trocar, or inner tube, quite into the sac, or if in entering it catch and tear or split up a fragile sac, more or less of the cystic fluid escapes into the

abdominal cavity, and forms one if not the chief cause of the fatality which sometimes follows this simple operation.

But should *injection* be attempted with an imperfect introduction of the protecting tube, whether that tube be the canula of the old trocar, or the outer tube of Mr. Wells's trocar, the result may be most disastrous. I have seen intense peritonitis occasioned by tincture of iodine thrown upon the peritoneum in such an attempt to inject an ovarian cyst, and Syme, in his "Principles of Surgery," noticing a like faulty injection for cure of hydrocele, remarks: "If the liquid is allowed to remain in the cellular substance, it gives rise to violent inflammation, and soon terminates in sloughing of the scrotum."

I have encountered on many occasions embarrassments similar to the above, and in common with others had tried to obviate the uncertainty of entrance of the *outer* canula, by cutting down to the bladder or tunica vaginalis, or pleura, or peritoneum, or whatever might be the immediate investment of the fluid to be evacuated; until it occurred to me to *reverse the relation* of the tubes to each other, and have the protecting tube on the *inside.* And while in Edinburgh, in 1871, I had a double, tubular trocar made by Gardner upon the following plan: The outer tube, smooth and of uniform size, has the distal end pointed and cutting like a lancet, so that it penetrates easily, and to any depth, without any need of previous incision of superimposed tissues; and the protecting tube, being now inside, may be advanced into the interior of the cavity, with absolute certainty of entrance, and without a possibility of even touching the margin of the aperture, or any of the tissues through which the outer tube has passed. The cutting edges must rise from the point of the trocar by a very acute angle, not more then 30° for the largest size and only 15° for the aspirator sizes; and the cutting-edges must be *very thin* and *sharp*, but of course sharp for only one-half the circumference of the tube, the half next the point, as if sharp all around a circular piece would be cut out, and a round hole left.

Instruments similar to the above were made under my direction by Krohne and Sesemann, in May of that same year, and were exhibited at the next meeting of the British Medical Association, in London, August, 1873. The largest size is noticed in Spencer Wells's recent work on "Diseases of the Ovaries," p. 336. But the smaller sized instruments seem to have been overlooked, for Mr. Alfred Goodrich, in a letter to the British Medical Journal, August 8, 1874, says: "In emptying a cavity with the aspirator the operator is often alarmed by finding the instrument filled with blood, arising from the walls of the collapsing cavity being forcibly sucked against the sharp point of the needle;" and he proposes, as if it were his own idea, that the trocar consist of two tubes, the *outer* one pointed, the *inner* one not so. But in the same journal for August 22, Mr. George Brown, of the Northeastern Hospital for Children, referring to Mr. Goodrich's suggestion of a trocar guarded by an inner tube, remarks: "The idea is not original; we have had one in constant use for more than twelve months, which was supplied by Messrs. Krohne and Sesemann." Now these excellent instrument-makers, in 1871, three years before this correspondence, constructed my instrument, which, in the catalogue of the museum at the forty-first annual meeting of the British Medical Association, was designated "Wells's Trocar improved by Fitch."

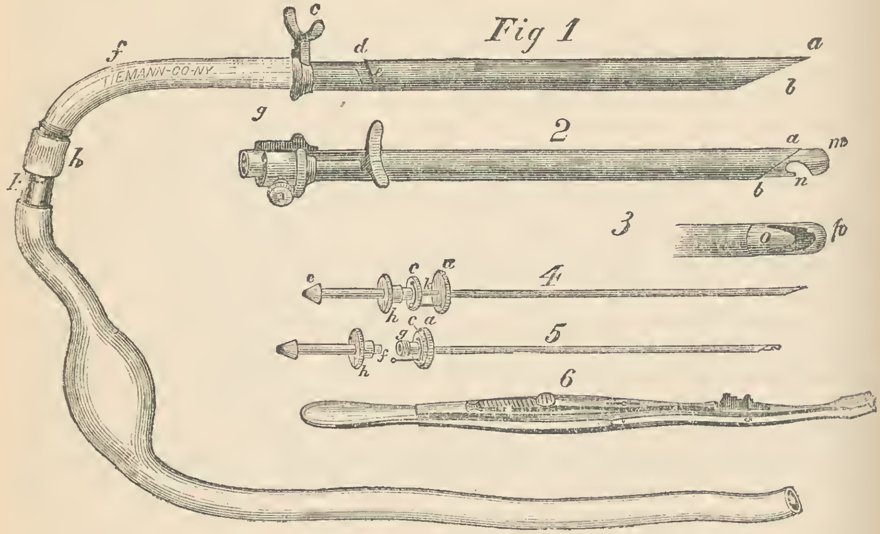
This instrument is not perfect; for, although the entrance of the protecting tube is rendered free from the possibility of failure, yet the *open*

end of this same tube is hazardous, especially in the aspirator-trocar, where it must be thin and sharp, to avoid bulk; thus in tapping the bladder, we dare not draw off the last of the urine, lest we injure the lining of the contracting viscus, and this danger is pretty generally felt by surgeons. In the August numbers of the journal just quoted, a correspondence appeared in reference to a successful paracentesis for hydrops pericardii, in which Mr. Singleton Smith, upon whose patient the operation had been performed, admitted the risk which accrued, not only from the unguarded point of the aspirator-trocar in the cavity of the pericardium, as the fluid was drained off, but also from the sharp edge of a canula rubbing against the pericardium, or coming into contact with the beating heart. About the same date, the Lancet, under the head of "Medical Facts," observed that in "tapping of the chest, when the fluid has been evacuated by the exhausting apparatus, the lung in expanding may strike against the sharp and hard canula. To prevent this, M. Béhier, of Paris, uses a canula of soft metal to be introduced into the ordinary tube, which, when the pleura is emptied, bends down against the parietes of the chest, and the lung does not suffer." Now a tube of soft metal cannot be drawn very thin, and, were it made large enough for the bore to be permeable to fluids, it would be too bulky to enter a small canula, and then coughing or other movement of the patient would be liable to throw the lung against the soft tube, and bending it down, stop the flow prematurely. Perhaps enough has been said and quoted upon this point, and upon the disadvantages of the open canula; I think we all feel the want of a safer trocar than any hitherto used.

I now announce a most important modification of the double tubular trocar, which avoids the danger of the open canula, and by which the instrument, while performing its highest achievements of discovery and cure, may be used as a trustworthy exploring probe and sound; and which will, I believe, in time supersede every other form of the instrument. Retaining my first improvement of making the outer canula the puncturing, or rather the incising, trocar, I have had the distal orifice, or open top, of the *inner* canula closed over by a rounded or dome-shaped roof, so that, when it is projected beyond the cutting point of the outer canula, the two tubes fit closely together, and the end of the combined instrument feels perfectly smooth like the end of a rectal sound, or catheter, or probe, and may be freely moved within the cavity penetrated, whether this be an ovarian cyst, a uterine fibro-cyst, the abdomen, the thorax, the bladder, a joint, or even the pericardium, without danger of wounding any viscus or organ, puncturing any vessel, or even scratching or abrading the lining of the cavity, or of any parts contained therein.

The base of this *dome* being of the same external circumference as the inner tube, of which it is the continuation, and fitting the outer tube accurately, there can be no escape of fluid till the dome is advanced or pushed out so as to occlude and shut out the cutting point of the outer tube; then there is disclosed by this movement a fenestra, or oval aperture on *the under side* of the inner tube, just below the roof, or dome, cut out of the lower wall and one-third of each side-wall, of the full size of the bore of the tube, and by which fluids may be freely evacuated or injected; the distal end of this segment is sloped off towards the dome, so that no obstruction can lie there, while at the proximal boundary a curved lip projects over one-third of the whole fenestra to prevent the possibility of obstruction; and the fenestra thus guarded, and being,

moreover, on the under side, cannot be stopped by the wall of the cavity coming into contact with it, nor by the falling upon it of any natural textures, or layers of false membrane, or flakes of plasma, as often happens with the open end of the old canula. If, while dis-



Figures 1, 2, 3, represent the ovarian trocar; 4, 5, the aspirator trocars; the intermediate sizes for paracentesis abdominis, paracentesis thoracis, etc., and the transfusion trocar, are sufficiently represented by one or all of these figures. Fig. 1 shows the cutting point (a b) of the outer canula advanced, ready for puncture, with the dome of the inner canula retracted, shutting the instrument just behind the point (b) against ingress or egress of fluid; c is the thumb-rest for projection and retraction of the dome by the thumb of the hand holding the instrument; d is a slot with a knob regulating and fixing the dome and point in any desired position; turning the knob one-half revolution into the proximal transverse slot allows the tubes to be separated for cleansing and oiling; f is a continuation of the inner canula, forming a tubular handle, which directs the current downwards—one end of an India-rubber tube is drawn over the lower orifice of this handle; k is a bit of glass-tubing by which the character of the fluid may be observed, or its absence noticed; the bulb is a simple expansion of the India-rubber tube (without valves or joints to interrupt the easy flow of fluid or to whip the blood in transfusion). Fig. 2 has the thumb-rest pushed forwards and turned into the distal branch slot, projecting the inner tube and dome (m), sheathing the cutting edge and point (a b) of the outer canula, and disclosing the fenestra (n) cut out of the under and side walls of the inner canula; n, in Fig. 2, and o, in Fig. 3, show the curved process of the lower wall of the inner canula, underlying the proximal third of the fenestra, to prevent occlusion from contact of cyst-wall, or vein-wall, or any floating substance. Fig. 4 is the aspirator trocar, with the dome retracted; Fig. 5 has the dome projected; e h is the nozzle; e the proximal end, over which the end of the India-rubber bulbous tube or the tube of the aspirator may be drawn; f the conical distal end to be inserted into (g) the funnel-shaped end of the inner canula, and fixed by a turn of the hose-coupling nut (h). Fig. 6. The clamp forceps for holding the sac upon the trocar during evacuation of the contents; also, for closing the orifice in the sac upon withdrawal of the trocar, and preventing leakage of cystic fluid into the peritoneal cavity.

charging the fluid for which it was introduced, there be found an aggregation of cysts, or a multilocular sac, this instrument may be used as a long artificial finger to examine the interior of the original cavity, and to feel for a proper place to enter, where it may be held till the cutting point is advanced to make an aperture for its introduction.

Thus, in ovariotomy, it will be found extremely convenient, the left hand supporting the tumor and the right holding the instrument,

which can be instantly changed, by an easy movement of the same hand, from a trocar to a sound, and *vice versâ*, to define and puncture cyst after cyst, until the bulk of the whole is sufficiently reduced to admit of withdrawal through the abdominal incision, with only one aperture in the cyst-wall first punctured, and this always occupied by the instrument which thus prevents leakage; and the dome-trocar may here be used, where the end of the open canula could not be with safety, to stir up and liquefy the loculose contents, and to break down such obstructions to the flow as imperfect septa and membranous intersections, while it still plugs the original aperture, thus preventing escape of cystic fluid into the cavity of the abdomen; and it oftentimes obviates the necessity of enlarging the aperture in the cyst for the introduction of the hand, which procedure should be avoided, as involving overflow of cyst-fluid upon the peritoneum.

In operating for hydatids of the liver or kidney, the dome-trocar, of aspirator size, may be used to loosen and dissever these little bodies while the aspirator is extracting them through the same instrument. And we may, with one of these smooth-ended instruments, of suitable length, search for and drain off the last drops of urine, during aspirato-puncture of the bladder, which we dare not do with the end of the open canula, much less with the sharp point of the ordinary single-tube aspirator needle; or, while the dome instrument is within the bladder, we may use it to explore the interior both before and after emptying it. In cases of intractably enlarged prostate, I believe that we may properly reach the bladder by perforating this gland with a dome-trocar having a less curve than an ordinary sound, and thus not only relieve the bladder at the time, but give permanent release from the oft-recurring retentions. I have forced a common strong catheter through the prostate in such a case; and the patient, who was previously nearly worn to death with his disability, is now enjoying a new prostatic bit of urethra, and is independent of instruments.

For explorations of bone, we may insert a probe-sized instrument, with the point projecting, till we reach the proper depth; then, advancing the dome, we have a harmless probe with which to search for caries or exfoliation, leaving only a capillary wound, without entrance of air or exit of blood. The dome, in all the sizes, should be solid or accurately floored over, to prevent lodgment of anything there which might impede its easy withdrawal from the cavity.

The life-giving operation of *transfusion* may, I think, be quickly and well done with this instrument. A short dome-trocar, of suitable size, having been attached to each end of an India-rubber tube a foot long, with the middle expanded into a bulb, one of the trocars is inserted into the vein which is to furnish the blood, and, when the apparatus is filled, the other trocar is introduced into the receiving vein, when the operation is completed. The tubes are closed and opened at their distal ends by retraction and projection of their domes, which prevents the possible admission of air; and no valve or stopcock is needed. The receiving vein should be exposed by a short incision, but the supplying vein will generally be sufficiently prominent to be entered without previous dissection. As soon as the lancet-end of the outer tube is inserted, the dome is projected, and the tubes thus guarded may be safely pushed as far as required, downward into the furnishing vein, and upward into the receiving vein, and no ligature will be needed. Thus time, so valuable

in this operation, is saved, disturbance of the vein is avoided, and injury to the interior of the vein need not be feared.

If the *mediate* method be preferred, a common glass, or hard India-rubber, or metal, syringe, with the piston removed, and the nozzle inserted into a flexible tube, armed with one trocar, will be a suitable reservoir into which the blood may be caught, as in ordinary venesection; or the blood may be defibrinated by whipping, and strained into the syringe; the dome with the open fenestra is left projected till the trocar fills, then it is retracted, closing the fenestra, and leaving the point of the outer tube ready for puncture. Upon inserting the trocar, we need not replace the piston, for sufficient and more steady propulsion may be obtained by merely raising the syringe.

The hole in the side of the nozzle, used by Mr. Wagstaffe, is liable to occlusion from the contiguous wall of the vein; in the dome-trocar this is obviated by a curved projection of the tube-wall over the proximal end of the fenestra, open at the sides, as previously described. In this operation it is very important that the dome be solid to prevent lodgment of clot.

The *aspirator attachment* deserves attention, for it can be applied to any syringe or exhausting apparatus; the adjustment is effected instantaneously and without moving either trocar or exhausting apparatus, or twisting the flexible, connecting tube, by merely pushing the end of the aspirator nozzle into the funnel-shaped end of the inner canula, and fixing it by one turn of a loose ring-nut, like a hose-coupling. The India-rubber tube connecting the nozzle with the aspirator has the usual bit of glass-tubing, so that the current may be observed or its absence noticed.

Some peculiarities of the different sized instruments should be mentioned. The *ovarian trocar* has a thumb-nut (for which I have to thank Dr. Thomas Keith), by which either the cutting point or the dome may be advanced or retracted, and fixed in either position by the thumb of the hand holding the instrument. The proximal end of the inner canula is prolonged into a hollow, curved handle, very convenient to hold by, while it also directs the current of the flowing liquid downwards; and one end of an India-rubber tube, three feet long (with a bit of glass tubing in it), may be drawn over the lower orifice of this hollow handle, to conduct the fluid into a receiving vessel; the middle of this tube is expanded into an elastic bulb, by which the flow through the tube may be promoted until the siphon current is established; and we may use it for washing out or for injecting the cavity. Mr. Wells's grapples may be slipped upon this trocar, or long, light clamp-forceps, with ring ends, may be used to seize the sac, upon or even before puncturing, and, held in the hand with the trocar, will accommodate themselves to the varying distances to which the trocar enters.

The *trocar for paracentesis abdominis* has a curved, hollow handle continuous with the inner tube like the ovarian trocar.

All the sizes below that for paracentesis abdominis, have their proximal ends adapted to the aspirator nozzle, and therefore a separate, curved, hollow handle is provided to fit all of them, and may be instantly fixed to either by a ring-nut, similar to that of the aspirator nozzle; and with this handle an India-rubber tube and bulb may be used, as with the ovarian trocar, when we wish to simply empty a cavity without the aspirator.

The instruments may be of any size. Of those which I have had made, the *ovarian trocar* is ten inches long, including the handle which is

four inches, with the internal diameter of the inner tube half an inch. Dr. Washington L. Atlee tells me that he has used one of these in his last forty-one ovariotomies, and expresses unqualified approval of it.

The *abdominal trocar* is six inches long, including two inches for the handle, the calibre equalling that of a No. 11 catheter of the American scale, 17 of the French. The *smallest sizes* correspond with Dieulafoy's aspirator needles; of these, two are each seven inches long, and fine, for the bladder and deep tapping; two are four inches each in length, and stouter, for hydrothorax, transfusion, etc.; one is short and very fine, for hydro-pericardium, spina bifida, etc.

UTERINE HEMORRHAGE DURING GESTATION.

BY

E. H. TRENHOLME, M.D., B.C.L.,

PROFESSOR OF MIDWIFERY AND DISEASES OF WOMEN AND CHILDREN IN BISHOP'S COLLEGE, MONTREAL; ATTENDING PHYSICIAN TO THE WOMAN'S HOSPITAL; FELLOW OF THE OBSTETRICAL SOCIETY OF LONDON, ETC.

THE object of the present paper is simply and briefly to point out a form of hemorrhage met with during pregnancy, heretofore unrecognized by writers upon midwifery. It is foreign to my purpose to speak of the subject in general, or even to recall to your minds some excellent papers that have lately appeared from the pens of the well-known and honored Dr. Fordyce Barker, and others.

I will first offer the history of the following case, as illustrating the subject:—

Mrs. N., æt. 39 years, and of English parentage, was a feeble, anæmic woman, of dark complexion, spare in flesh, and of a lymphatic temperament. She had been married some sixteen years, and was the mother of five children, the youngest of whom was eight years of age. She had been deserted by her husband after the birth of her last child, but he had returned to live with her during November and part of December, 1874, after which time he had taken his final departure for parts unknown. The menstrual flow had appeared as usual in January, 1875, but for the first time had been rather profuse, and had never entirely ceased; although the hemorrhage had moderated between the terms, it had been increasingly severe at each period up to the removal of a dead fœtus, of about the size of a third or fourth months' child, on August 7, 1875. For some months the patient had had constant pains in the uterus, of a sharp cutting character, and, as she remarked, "not at all like labor-pains." The condition of the patient, and the persistence of the pains, with the bleeding, led me to suspect malignant disease of the organ.

To make a diagnosis, the os was dilated sufficiently to allow the introduction of the index finger, when I felt a globular body, well up in the cavity of the uterus, and barely accessible to the touch. Dilatation of the os was continued until the greater part of the hand could be introduced. From the outset there were no indications of the presence of the decidua; the mucous membrane around the lower segment of the uterus was smooth and glossy to the touch; the cavity of the womb was found to be occupied by a projecting body somewhat like a large sessile tumor, with its base toward the right side, and occupying about one-quarter of the superficial surface. This body was felt to be a fœtus in its amniotic and epichorial decidual envelopes; the point of coalescence between the epichorial and parietal deciduæ was easily recognized.

The condition of matters having been determined, the membranes were ruptured, and the fœtus with its placenta removed. This, however, was not effected without difficulty, as the epichorial membrane had to be forcibly separated at the point of its uterine attachment; the sensation felt in so doing was very perceptible and characteristic. The parietal decidua was in no way interfered with by the delivery thus accomplished. The uterus contracted well, and the patient made a good recovery without any subsequent return of hemorrhage.

The uterine decidua has been the centre of attraction to many able investigators during the past few years. Much has been done toward elucidating its anatomy and physiological functions. The changes, truly marvellous, that occur during ordinary menstruation are somewhat definitely known. From this basis, so well established, we may reasonably hope for rapid advancement in the successful treatment of uterine disease, and from the same source we may expect to obtain hints for the more correct appreciation of some of the pathological conditions met with in pregnancy.

To understand the irregular development and behavior of the mucous membrane, we must bear in mind its regular and normal course in gestation. This course may be briefly stated as follows: (1) Hypertrophy and folding of the mucous membrane preparatory to the reception of the impregnated ovum; (2) The imbedding of the ovum in the decidua, and the consequent dividing of that membrane into three, viz., the utero-epichorial, the epichorial, and the parietal deciduæ; (3) The subsequent union of the epichorial and parietal deciduæ, forming one homogeneous membrane. As soon as this is accomplished, the uterine cavity is perfectly occluded, and any discharge from the interior is impossible.

A normal conception and gestation must proceed in the above order; when any serious deviation occurs, difficulties must follow; deficient vital action, and excessive vital action, alike work mischief. In the latter case, a fold of the mucous membrane may protrude into the canal of the cervix, or even pass outside the external os; a case of this nature came under my notice a short time ago, in which the protruding mass appeared to be a plug of tenacious mucus; and it was only when this was forcibly removed that the nature of the case became known. I need hardly say that abortion followed. On the other hand, deficient vital action is followed by imperfect development of the membrane, and an absence of that perfect union of the epichorial and parietal deciduæ which takes place in normal pregnancy. This form of abnormal development is met with, as might be expected, in anæmic and exhausted women; it also occurs in those of apparently good, general health, but whose vital powers have been exhausted by too frequent and rapid gestations. Nature tries to meet the requirements of the case, but her powers are too feeble to do so efficiently.

The epichorial decidua, being deficient in vitality, fails to enlarge and allow the embryo fair scope for development. The envelope acts as a compressor, forcing the fœtus toward the placental surface, and at the same time interfering with its nutrient supply and growth. The ovum and its envelopes, in fact, form a sort of sessile tumor, such as was noticed in the case referred to.

The muscular structure of the uterus is apt to be excessive in growth, and not deficient, as at first thought we might be inclined to suspect: we know, however, that hyperplasia or subinvolution are not indications of excessive vital activity, but rather the reverse; most probably it will be found that subinvolution is markedly present. Clinical facts indicate this view as probably correct. In the case mentioned, the uterus was much larger than was necessary for the accommodation of the fœtus. There was no impediment to the escape of any fluid from the left Fallopian tube to the vagina, a condition which would permit of free menstruation if that function could really be performed during gestation, which I very much doubt. That hemorrhage can really occur from the cavity of the uterus, and that, too, from a decidua of pregnancy without

causing abortion, is quite possible, and need not be doubted; perhaps we have in this condition the clue to the mystery of super-fœtation.

The purport of these remarks is to explain the cause of the uterine hemorrhage met with during gestation. The form of gestation and the condition of the uterus itself give an easy solution to what has heretofore been inexplicable; the exact point or points of hemorrhagic escape will undoubtedly be ascertained hereafter. The condition of the enlarged uterus, the character of the mucous membrane, and the unnatural and irregular strain upon the organ, are sufficient factors to account for the monthly and continuous flow of blood referred to. We know that sessile and submucous tumors are frequent causes of uterine hemorrhage, and as this form of pregnancy resembles these cases in their chief outlines, it is naturally followed by similar results.

As to treatment, I have but little to say. When we meet with such pregnancies, whether complicated with metrorrhagia or not, it seems to me that the proper treatment is to induce abortion. Apart from the exhausting hemorrhages, cases are met with in which the uterine distress and constitutional disturbance are so great as to urgently demand our interference; there is little ground for hesitancy in the matter, as we cannot reasonably expect a normal termination to an abnormal gestation.

The following conclusions seem to be justified by what has gone before:—

I. That an abnormal development of the uterine decidua is not apt to occur.

II. That hemorrhages other than those of placenta prævia can take place from the cavity of the gravid uterus, only in cases where there is an abnormal condition of this membrane.

III. That menstrual hemorrhages can take place from the cavity of the uterus without accompanying abortion.

IV. That this condition might permit of superfœtation.

V. That the treatment indicated in such cases of gestation, when the uterine and general distress are great, is to remove the products of conception, whether such distress is or is not accompanied by metrorrhagia.

CHRONIC INVERSION OF THE UTERUS.

BY

JAMES P. WHITE, M.D.,

PROFESSOR OF OBSTETRICS IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

In introducing the subject of Chronic Inversion of the Uterus to the Section on Obstetrics, I propose simply to bring prominently forward facts and conclusions already in a great measure laid before the profession, and to urge the claims of the operation described to the confidence of this representative body.

Never having witnessed the occurrence of the accident in question, I will not attempt to describe its causes or the manner of its occurrence, but shall consider chiefly the question of treatment or restoration. The gravity of the accident and the sad condition of its victims will be conceded by all who have observed the miserable state of those suffering from its effects. Without discussing the possibility of spontaneous reduction, which has been asserted by one or two recent writers to sometimes take place, it certainly does not occur with sufficient frequency to warrant delay in our efforts for artificial reposition, in the expectation that a cure will be effected by the unaided efforts of nature.

Until quite recently, inversion of the uterus, unless restored within a short time after its occurrence, was regarded by all writers as entirely incurable, and the unfortunate female was left without hope of restoration, to drag out a loathsome existence. So miserable has the sufferer from this terrible accident been made by it, that relief by extirpation of the organ, with all its attendant dangers, and consequent deformity if succeeded by recovery, has been acceded to as preferable to living on in this deplorable state. Meigs, I suspect, at the time he wrote gave very briefly the sentiments of the profession in relation to the practicability of restoration, in his "Letters to his Class," on the diseases of females. Speaking of a case of six months' duration, after describing the feeble and exsanguine condition of the woman, he says:[1] "What are you to do for the patient? Will you reposit or reinstate this womb? You can't. You might as well try to invert one of the non-gravid uteri on my lecture-room table as to reposit this one. The time is gone by. You have no art or skill, nor any power equal to the performance of such a miracle of surgery as that." All the authorities of the same date regard the reposition of the uterus, after involution, as highly improbable, and do not direct any efforts to be made for its restoration. Churchill, Ramsbotham, Velpeau, and Bedford content themselves with directing such measures as will contribute to the comfort of the woman, and with suggesting that removal of the organ may, in extreme cases, be resorted to. Notwithstanding the success which has attended the operation for reduction of the inverted uterus during the last few years, especially in America, the more recent writers still seem incredulous. They continue to give the same directions for the alleviation and treatment of this con-

[1] Letters to his Class, by Charles D. Meigs, M.D., page 232.

dition that are to be found in the older authors. I have myself treated by reduction, since March, 1856, twelve cases of uterine inversion, varying in duration from immediately after the occurrence of the accident to no less than twenty-two years. Reduction in all was effected at the first effort, and, as far as could be ascertained, without laceration of tissue. By similar measures other gynæcologists in this country and in Europe have repeatedly succeeded in accomplishing reduction in cases of chronic inversion, and yet the feasibility of the method is by no means uniformly admitted by writers and practitioners at the present day.

Thus, Leishman, whose recent work on Midwifery is justly regarded as high authority, at first hesitatingly admits that "elastic pressure alone, or aided by incisions in the neck, will overcome every case of inversion except when fixed by inflammatory adhesions," but subsequently goes on to describe the method of removing the uterus "when the doom of the patient seems fixed;" and adds, under such circumstances, "we can have no hesitation in resorting to a measure so extreme as the removal of the organ."[1] Schrœder, a German authority whose work has been translated and published in this country, dismisses the whole subject of chronic inversion by saying, "Reposition is easy as long as the os is not yet firmly contracted; otherwise great difficulties may be met with, and repeated trials under chloroform may become necessary."[2] Meadows, in England, in his Manual of Midwifery, says: "When the case has remained unrelieved for many weeks, though attempts should always be made to secure reduction, etc., yet the chances are very greatly against success." Courty says that, if reduction be impossible, it will be necessary to resort to palliative treatment or to extirpation of the uterus for its radical cure. Dillinger, in a work republished in London in 1871, says: "Chronic inversion is held to require palliation; if that is vain, removal by ligature or excision." Barnes, of London, thinks it necessary to invent some new operative procedure, in order to avoid "the various methods of amputating the uterus, or of effecting *forcible* reduction, as by Professor White's method," etc., and accordingly recommends incisions in the neck, and gives a plate of an elastic pessary, to aid in effecting gradual pressure. He very justly admits the failure of elastic bags in the vagina, as they, when distended, stretch the vagina excessively, require a firm *point d'appui* in the perineum, which cannot always be had, and also fail to exert pressure upon the fundus with sufficient force and directness. He might also have added, in relation to the elastic bags, that they produce painful pressure upon the rectum and neck of the bladder, and cannot be borne by the patient for any considerable time.

In the abstract of Society proceedings, given in the Obstetrical Journal of Great Britain and Ireland, republished in Philadelphia, in the August number, 1873, will be found a very full report of a discussion in the Obstetrical Society of Dublin, on the subject of chronic inversion of the uterus. Two cases, of six and seven months respectively, were reported by Drs. Kidd and Johnston, giving rise to a debate on the subject in which several members present participated. Dr. McClintock, in the course of his remarks, said that he was satisfied that cases would arise where all manipulations would entirely fail to replace the organ. The President, Dr. Evory Kennedy, said that, in dealing with these cases of

[1] Leishman's System of Midwifery, American edition, p. 417.
[2] Manual of Midwifery, American edition, page 315.

inversion, they could not classify them merely as acute and chronic. He thought there was an intermediate stage, in which it was *just possible* to reduce by compression the uterus back into its place, but when that stage was passed, the thing became *impossible.* He looked upon it that up to four or five months after the accident the case was not a chronic one, and that facilities still existed for reduction which did not exist at a later period. Again, that he was not aware of reduction having been effected after fifteen years. He thought that the condition of the tissue would be so altered in the course of ten or fifteen years that it would be totally impossible to effect reduction at the end of that time.

In the January number of the Obstetrical Journal, for 1876, a description of the amputation of an inverted uterus is published without one word of editorial comment. It was of only three months' standing, and was excised with the *écraseur* by Professor Martini Barta, as the only means of arresting the hemorrhage incident to this condition. During the present year also, I find published, in the American Journal of Obstetrics, an article "On Ablation of the Body of the Womb in irreducible Uterine inversion, by External Hysterotomy," by M. Donné, of Paris. This paper, which was read before the French Academy of Medicine, arrives at the conclusion that external hysterotomy is an extreme surgical resource, but precious in cases of *irreducible inversion.*[1]

But it is useless to multiply citations illustrative of the hesitation and prejudice which still prevail on this subject, recommending, as several authors do, for the relief of uterine inversion, an operation of much greater danger to the patient than reduction, and one which leaves her, when she escapes with her life, in a sadly mutilated condition.

Whence this almost universal want of confidence? The cases of reduction are now so numerous, and the operation, in my opinion, so demonstrably practicable, as not to admit of doubt. I am utterly unable to account for this unbelief, and feel, therefore, justified in detaining you with a brief history of the steps by which I arrived at a different conclusion. Some remarks upon the method of operating, and a reference to three illustrative cases, will also be added.

There may be found in the Buffalo Medical Journal for March, 1856, an account of a case of inversion of eight days' standing which had been reported, with a description of the successful operation for its reduction, to the Buffalo Medical Society in the preceding February. I concluded that article with the following remarks: "This case is regarded as interesting in many respects. It will encourage the growing belief among accoucheurs that reduction may be undertaken with reasonable hope of success, at a period much later than most writers have heretofore advised." In the same article, alluding to a case of fourteen days' standing which had fallen under my observation long before (in 1842), and in which, in accordance with the teachings of that day, no attempt at restoration had been made, I added: "With my present views upon this subject, I should abandon such a case as hopeless only after a long effort at reposition." Fully convinced, from the result of the efforts made in this instance, eight days after inversion, of the feasibility of restoring the uterus in many cases heretofore considered irreducible, I did not meet with an opportunity of putting my convictions to the test until March 12, 1858, when I visited Mrs. M., near Hornellsville, N. Y., who had been confined on the 22d of September previously, almost six months before, and, after

[1] American Journal of Obstetrics, June, 1876, page 348.

about one hour's continuous effort, succeeded in repositing the uterus, which had been completely inverted. A full account of this case, with illustrative plates and a description of the manner in which reduction was accomplished, was published in the July number of the American Journal of the Medical Sciences for 1858. Permit me to crave indulgence for one word in relation to priority in this operation. Tyler Smith, in London, on April 24, 1858, published in the London Medical Times and Gazette an account of a successful operation for inversion. But I submit that this was forty-two days after my operation in Hornellsville, and more than two years after I had taken the initiative and had published my views and "hopes," in connection with the report of a case of eight days' duration.

Upon this point, I trust that I shall be pardoned for gratefully quoting the following passage from an able article on this subject by the late Dr. Henry Miller, the impartial and distinguished Professor of Obstetrics in the University of Louisville:[1] "Before I proceed to do this [give an account of the method of manipulation pursued by Dr. White], it is meet that I should pay a tribute of honor to our countryman, Professor James P. White, who has not received the credit he so well deserves for his leadership in the revolution of gynæcological practice which he inaugurated." The writer then proceeds to a careful analysis of the facts which led him to the above conclusion, which it is unnecessary here to detail.

On August 24, 1858, in the presence of Professors Austin Flint, Austin Flint, Jr., Thos. F. Rochester, W. H. Mason, and others, I reduced an inverted uterus of over fifteen years' standing. A full account of this case, as reported to the Buffalo Medical Association, with the remarks of the above-named distinguished gentlemen, will be found in the Buffalo Medical Journal for October, 1858. The difficulty encountered in the operation bears no proportion to the duration of the inversion. I believe it to be as difficult to restore the uterus immediately after complete involution has taken place, as at any subsequent period. In No. 9 of my series, a case of only six months' duration (at Port Dover, Canada, reported to the Medical Society of the State of New York, and published in the Transactions of that body for 1872), reduction was far more difficult than in the case of fifteen or in that of twenty-two years. In the case of six months, two protracted efforts, under chloroform, had been made before I saw the patient; each attempt had been succeeded by some peritoneal inflammation, and it was the opinion of all present at the final operation that reduction was protracted in consequence of firm adhesions of the uterus to the surrounding tissues. The same difficulty was encountered in my tenth case, one of nearly seven years' duration, in New Bedford, Mass. At an early period in the history of this case, as will be seen by the excellent report of Prof. Bixby, the *écraseur* had been applied, and such pressure made as resulted in breaking the chain of the instrument, the operation being succeeded by inflammation, which produced adhesions. The remark of Evory Kennedy, that "the organ undergoes such change in process of time as to render reposition impossible," is not well founded. The uterus becomes as small and inflexible immediately upon the conclusion of involution, which, according to the best authorities, occurs within twelve or at most sixteen weeks after delivery, as at any subsequent period

[1] Thoughts on Chronic Inversion of the Uterus, specially with reference to Gastrotomy as a substitute for Amputation of the Uterus. By Henry Miller, M.D. Richmond and Louisville Medical Journal, April, 1870, p. 14.

before the menopause. Reduction, therefore, at the expiration of twenty years, is not more difficult than after the same number of weeks, as far as the manipulation of the organ itself is concerned.

There is, however, an intervening period between the commencement and the conclusion of the process of involution, when the organ must, in my opinion, be handled with more care. Whilst undergoing this change, the uterus does not possess the firmness and elasticity of the unimpregnated organ, nor the muscular flexibility and toughness of that at full period of gestation. Whilst in this transition state, undergoing the process of fatty degeneration, it is, I apprehend, far more brittle and liable to rupture than after this change is fully accomplished. In the cases in which the operation was resorted to at eight days, at three weeks, and even at five weeks after delivery, as in my eighth case,[1] the organ did not possess the firmness of normal uterine tissue in the unimpregnated state. In the report of the last case (eighth) will be found the following remarks: "Indeed, I am induced to suspect that at this period after delivery the uterus cannot be subjected, without danger of laceration, to manipulations which would be perfectly safe at a later period after complete involution has taken place. The sensations occasioned by pressure were such as to excite apprehensions lest the tissues should yield under the fingers." It may be added also that this was the first case in which the repositor was used, and the safety of the structures may be attributed, in part, to its aid during the operation.

It will probably be found safer, in view of this friable condition of the tissues after the commencement of involution, to wait for the completion of this process, notwithstanding the increased difficulties of the operation occasioned by such delay. Priestly, in his lectures on the subject of the involution of the uterine parietes, assures us that "with the advance of the fatty transformations, the uterus becomes in a corresponding degree friable, and continues so until it has completely returned to its normal condition," and that "it is occasionally so soft and friable whilst affected by this fatty degeneration, that a sound passed into the uterine cavity might be readily pushed through the uterine walls." The impression given whilst manipulating the uterus in the course of involution confirms these remarks of Dr. Priestly, and leads me to suspect increased danger in all operative procedures upon the organ during this physiological process.

In relation to the *modus operandi* of the operation of reduction, there is little to be added to the description given in 1858, of the manner in which reposition is accomplished. There seems great and unnecessary ambiguity and confusion on this subject. In all recent cases, the fundus uteri can be pressed into the body and neck, or "dimpled," as it is termed, by pressure upon the most depending part. In this manner I am certain that the two cases which were reduced immediately after delivery, and to some extent that of eight days' duration, were carried up. In the case of Dr. Lockwood's patient, in 1861, the womb had been inverted for about forty minutes when I arrived. Administering some paregoric and brandy to relieve the patient's semi-collapsed condition, I seized the uterus, pulled off the partly adherent placenta, and passed my hand, with the fundus before it, up through the neck and into the

[1] Report of two cases of Chronic Inversion of the Uterus, with a description of the Uterine Repositor. By James P. White, M.D., Transactions of the New York State Medical Society for 1872, page 200.

cavity of the replaced womb, with scarcely more difficulty than would be encountered in inverting a wet bladder. Retaining my hand there for a short time, contraction soon came on under the influence of the ergot and stimulants which had been freely given. The patient made a good recovery, and has since borne children. So with the case of eight days, it is stated in the report that, "having succeeded in 'dimpling' the fundus, pressure was maintained with the thumb at that point until the hand had become nearly powerless. To preserve this depression whilst the muscles of the hand were permitted to rest, a rectal bougie about twelve inches in length and one inch and a fourth in diameter, was carried along in its place, fixed in the dimple, and pressure unintermittingly continued through it, by the left hand outside the vulva. Gradually, the concavity of the fundus was found to be deeper, until it finally became completely restored."

This is doubtless the manner in which reduction takes place in all recent cases, whilst the organ is large and the walls flexible, and I was at first led into the error of supposing that this same method obtained in all cases. This delusion was, however, completely dispelled by my first case of chronic inversion, of six months' standing, in the account of which the following description of the method of reduction is given.

"There can be no doubt that the os first commenced to yield, and pressed down upon the intra-vaginal hand, which, it will be recollected, inclosed the entire body and fundus of the uterus, and the upper extremity of the bougie, and kept them in contact. This part [the os] gradually dilated, and passed down upon and over the neck, which in turn dilated and doubled down upon itself. The fundus did not perceptibly dimple in its centre or at either Fallopian orifice, and was not reflected upon itself during the operation. The organ was too firm, and the cavity too small, for any depression to be made upon the walls of the fundus. In recent cases, on the contrary, reduction may doubtless be effected by doubling-in, or dimpling, the fundus, and using it as a wedge to dilate the neck and os. That reduction takes place in all cases after complete involution by thus dilating the os and reflecting it down over the neck and body consecutively, has been several times verified by examinations made by competent observers, as well as by myself, during the progress of these operations. The uterus and vagina in complete inversions represent a continuous bag or sac doubled or reflected upon itself, with the open extremity of the sac securely fixed. Pressure upon the closed end of the bag (the fundus) will, it is plainly perceived, under such circumstances, result in straightening the bag by completely turning it the other side out. So with the parts concerned in inversion. Pressure upon the fundus, if gentle and well directed, pulls open first the mouth of the womb, then its neck, and finally, if persevered in, doubles the body upon itself also, and carries the fundus through the os, and neck, and body, to its normal position."

I have nothing to change in this description, given twenty years ago, of the *modus operandi* of reposition in chronic inversion. In the cases of fifteen years' and of twenty two years' standing, the attention of the distinguished gentlemen who were present was called to this fact (the reflection of the os upon the neck and body), and they were requested to pass a finger up beside the hand of the operator and verify the observation. Similar careful examinations were made by those present at the two most difficult of all my reductions, that at Port Dover, Canada, and that at New Bedford, in both of which peritoneal inflammation had been excited by previous surgical interference, resulting in adhesions, and in both also the same relation of parts was ascertained to exist during the progress of the operation. In my opinion it would be unwise

to double in the fundus upon the body, after complete involution, even if it were practicable to do so. The size of the tumor to be carried up through the cavity of the neck and os, would be increased by this introflexion, and would, by just so much, augment the difficulty of reduction. Any one who may make the effort to dimple the fundus of the unimpregnated uterus into the cavity, will perceive that it is impossible to effect reduction or inversion in this manner even upon the dead subject.

By this explanation all the apparent discrepancies, as to the manner of reduction, can be reconciled. One practitioner has operated on a recent case, and restored the womb by dimpling in the fundus, whilst his no less observing and truthful fellow has restored the involuted organ by reflecting the os over the neck and body, without at all being able to depress the fundus.

It is incorrect for Dr. Barnes to call the procedure just described, "a forcible reduction." I submit that there is no conceivable method of dilating the os and neck of the uterus less forcible than that of making gentle, elastic pressure upon the fundus, producing thereby equable and moderate traction by the vagina which is attached within the os in complete inversion. The vagina pulls open the os with less liability to laceration than the pressure of the tent, the India-rubber bag, or any other mechanical means can do. Does any gynæcologist of the present day hesitate to dilate this canal for the removal of intra-uterine growths? Does any uterine pathologist believe that it would be impossible safely to dilate the os and bring down the fundus of the uterus—completely inverting the organ—if carefully and perseveringly undertaken? If these questions are affirmatively answered, why may we not *pull open* the neck by means of the vagina in the same gentle manner as we could *press it open* when in a normal position, and thus carry the fundus up through it by means of pressure upon that part when it is in a downward direction? Perhaps I may be too sanguine, but my present belief is that well-directed pressure upon the fundus, if continued long enough, will, in all cases, unless prevented by firm adhesions, result in restoration or reposition, no matter how much time may have elapsed since inversion has occurred. Observation and careful reflection based upon the cases which have been committed to my charge, now numbering twelve in all, and varying in duration, as already stated, through nearly a quarter of a century, confirm me in the opinion first expressed in 1858.

Indeed my convictions are very decided, and I am incredulous as to the necessity of ever resorting to amputation, or to the still more objectionable operation of gastrotomy. True, the womb may not always be reduced at a single sitting, as in all the cases which I have encountered; but, by means of the "repositor," uniform and gentle pressure can be maintained until the os is fully dilated and the fundus pushed up through it. The insurmountable difficulty heretofore has been supposed to consist in our inability to maintain uniform and persistent pressure for a sufficient length of time. The hand would soon become fatigued, and another hand, even of the same individual, could not be substituted without losing a part of what had been gained. This loss is increased when the hand of a fellow practitioner is introduced to continue the operation. No doubt great physical endurance, being able to maintain one position for a great length of time, has been an essential element of success. The various substitutes which have heretofore been resorted to for continuing pressure when the operator has become exhausted, have utterly failed. The elastic bags, so often called in requisition, press more upon the viscera

resting upon the large surfaces anteriorly and posteriorly situated, than upon the fundus, which has no firm ossific base of support as have the rectum and bladder. The uterus ascends very soon, owing to the yielding nature of the vagina and perineum, and escapes from the reach of the distended vaginal bags. The repositor (which will soon be described), when it is deemed better to proceed in a more gradual manner, or when it may be found impossible to effect reduction by a single effort, can be received with the uterus into a large cylindrical speculum, and, by means of a "T" bandage, can be made to press directly upon the fundus until the os is gradually dilated and all resistance overcome. By means of the large spring at the outer extremity, the amount of pressure can be graduated to an ounce. The disk of this instrument will follow up the fundus, without compressing painfully the urethra or rectum, by means of this continuous elastic pressure in the upward direction, until the fundus disappears in the os and neck. Any intelligent assistant can be trusted to increase or diminish the pressure, during the absence of the operator, as the exigencies of the case may demand.

The construction and action of the "uterine repositor" will be readily understood by reference to the accompanying wood-cut, Figs. 1 and 2.

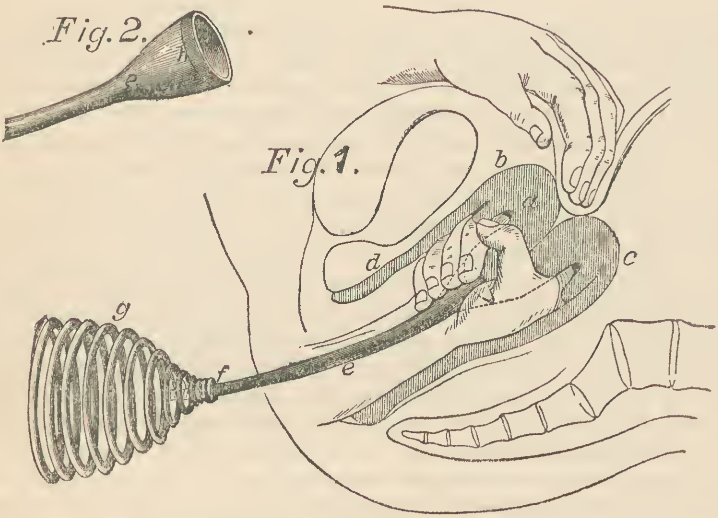


Fig. 1. *a*. Uterus in process of reduction. *b*. Anterior lip or wall of the uterus with the fingers of the left hand pressing upon it and assisting in pulling open the uterine cavity. *c*. Posterior uterine wall semi-reflected. *d*. Anterior vaginal wall. *e*. Wooden or hard rubber stem of Repositor, its enlarged extremity held in contact with the fundus by the intra-vaginal hand of the operator. *f*. Distal extremity of stem made into a screw, so as to be fastened into *g*, a coil of No. 11 steel spring wire, requiring eight or ten pounds pressure by the breast of the operator, against which it is placed, to bring it down.

Fig. 2. *h*. Uterine extremity of stem *e*, which is terminated with a soft India rubber disk $1\frac{3}{8}$ inch diameter, the concavity into which the fundus is received being about one-half inch deep, with its terminal margin thin and soft.

The instrument is composed of a stem of wood or hard rubber, curved to conform to the vaginal curvature, with a coil of steel wire attached to the outer extremity, whilst the other end is expanded and hollowed so as to receive the fundus of the uterus in its concavity or disk. The edge of this disk is tipped with soft rubber, being an inch and three-eighths in diameter, and about half an inch deep. The concave extremity of

this instrument is carried up into the vagina and placed in contact with the fundus, and then firmly held by the hand in the vagina. The outer end of the instrument, or coil of wire, is placed against the breast of the operator on the same level with the uterus. By means of this large circular spring, the instrument readily keeps its place on the clothing of the operator, and leaves the other hand free to be used above the pubes to assist in fixing the uterus and assist also in forcing open the dilating os, which can ordinarily be plainly felt through the abdominal walls.

The spring at the outer end of the instrument enables the operator without danger of lacerating the tissues to keep up a constant gentle pressure upon the fundus, and by leaning forward to increase this pressure intermittingly. The force thus exerted is applied more directly upon the fundus by means of the repositor than would be possible if the thumb and fingers were used, or the round end of the large bougie. I have often been delighted, since I have used the repositor, to find that it gave me a third hand which did not become fatigued, and which permitted me to use the left hand in manipulating over the hypogastrium, while the right easily held the instrument in contact with the fundus, and firmly grasped that part of the uterus which was not yet reflected, and which remained in the vagina. The disk, in which the fundus rests, is less likely to bruise or lacerate the organ than any other mechanical appliance. The intra-vaginal hand compresses the body and fundus, and lessens its vascularity, whilst something is gained by intermitting the pressure, also lessening by its use the exhaustion incident to unintermitting muscular effort on the part of the operator.

It may be well to state that the patient is always placed at the side of the bed with the feet resting in the laps of intelligent assistants, each of whom is also charged with the care of the knee and hand of that side. The hips of the patient are brought quite to the edge of the bed, which is raised so as to bring the parts on a level with the breast and arms of the operator. He should occupy the space between the extremities of the patient, resting upon his knees. This position gives him greater mobility than the sitting posture, and is much less fatiguing than standing. It is best to manipulate the uterus freely, thus rendering it more flexible and lessening its vascular congestion, before commencing the effort of restoration. The back of the hand should rest in the concavity of the sacrum, and should be completely introduced into the vagina, the body and fundus of the uterus with the upper end of the repositor being firmly grasped in the palm. The anæsthetic should be entrusted to a competent practitioner, and should be carried not only to insensibility, but as far as it can be without danger. It is unnecessary to add that the operation should never be undertaken without having had the patient's bowels completely evacuated a few hours previously. It is also unnecessary to say that it should not be undertaken during the menstrual flow. Sometimes, however, the hemorrhage is so continuous that the menstrual epoch is not well marked, when the operation may be proceeded with without fear of dangerous hemorrhage. It is remarkable, in view of the slight causes which usually give rise to hemorrhage in most cases of inversion, how little blood is lost during the manipulations incident to restoration. This is doubtless in a great measure due to the fact that the bleeding is controlled by the compression exerted by the hand around the body and fundus. Nor, if the manipulations are gently and carefully practised, is the danger of metritis by any means as great as might be expected.

I shall now give the histories of three typical cases, one of six months',

one of seven years', and one of twenty-two years' duration. In order to secure confidence in the feasibility of the operation, and avoid the bias which inevitably attaches to the observation of an enthusiast, I have selected two which were kindly reported by distinguished gentlemen who witnessed the operations. The first case is one of six months' duration, and the first in which I effected reduction after complete involution, although I had already successfully treated two cases of much shorter duration.

CASE I.[1]—On the third of March, 1858, Dr. C. D. Robinson, of Hornellsville, wrote to me that he "had been called in consultation with a neighboring physician, and found a patient with an inverted uterus of more than five months' standing." My opinion was desired as to "the possibility of returning the inverted organ and the propriety of extirpation." In my reply, the impropriety of removal, unless as a last resort, was insisted on, and the hope expressed that a prolonged and well-directed effort might succeed in reduction; and it was said that, in my belief, it was due to the poor woman that the attempt should be made before she was abandoned to the evils of chronic inversion. A few days subsequent to this date, I was requested to visit her at my earliest convenience. Engagements in the city prevented my complying with this request until the twelfth of March. On accompanying Dr. Robinson to the residence of the patient, Mrs. A. M., I found her extremely anæmic, confined to her bed, and suffering greatly from the loss of blood.

The history of the case, as furnished by herself, her husband, and the medical gentlemen who had been in attendance, was as follows: At the age of 30 she was taken in labor at the maturity of her second pregnancy, on the 22d day of September last, Dr. Batten in attendance. This labor was natural to the conclusion of the second stage, when she gave birth to a large male child. Placenta adherent, but removed at the expiration of about thirty minutes, and its delivery followed by copious flowing, severe pain, and faintings. The prostration was so great as to require the constant use of stimulants during the succeeding forty-eight hours, and for three weeks she continued extremely weak and faint. At about this time she took an aloetic cathartic, which occasioned violent efforts at stool, accompanied by pains resembling those of labour. Profuse hemorrhage followed these straining efforts, and a large pear-shaped tumor made its appearance through the os externum. The neck or smaller extremity of this body was at the vulva, and the larger extremity down between her thighs. By the assistance of her husband, she was enabled to return this tumor within the vulva, when a messenger was dispatched for Dr. Batten. Dr. B., upon his arrival, introduced his hand into the vagina and carried the uterus high up into the pelvis, and resorted to astringents and cold for the purpose of arresting the flow of blood, which continued profuse and difficult to control. The prostration being at this time very great, the horizontal posture was enjoined, stimulants and tonics were given, and the bowels were moved by enemata.

During the succeeding three months she had occasional hemorrhages, which were severe, with constant discharge of muco-sanguinolent matter. Two or three times, during this period, she so far improved as to walk about her room and partially supervise her domestic affairs, though looking very pale and being very feeble. About the middle of January she had another severe attack of hemorrhage, the tumor again presented itself externally, and was again returned as before; that is, pushed back within the vulva. Dr. B. again visited her, and prescribed such remedies as seemed necessary to control the flowing. Since about the first of February she has been compelled, from the debility consequent upon the exhausting, sanguinolent and leucorrhœal discharges, to preserve the recumbent posture. Lactation, doubtless, has added

[1] Vide Amer. Journn. of Med. Sciences, July, 1858.

to the exhaustion, and being confined to her bed she has little appetite, the stomach is irritable, and the bowels are costive. Ever since the patient took the aloetic cathartic and the tumor made its first appearance between the thighs, she has been aware of the existence of something unnatural in the vagina. This body has occasionally made its appearance externally, requiring the assistance of her husband to replace it, and she has had frequent attacks of a "straining sensation" described as accompanying its first complete descent. She has suffered greatly from all the symptoms arising from exhaustion and from sympathy with the uterine irritation necessarily developed by the malposition of the womb. The pulse now numbers 130; she is blanched or wax-colored, and grows dizzy and faint when raised to the semi-recumbent posture, and cannot be moved without experiencing a sense of prostration. It should have been stated that, on February 25, Dr. Robinson, of Hornellsville, and Dr. Reynale, of Dansville, visited the patient in consultation with Dr. Batten, when inversion of the uterus was diagnosed, and measures calculated to ameliorate her condition were resorted to.

Upon making a careful examination (nearly twenty-five weeks having now elapsed since confinement), the fundus of the uterus is found just within the os externum, and about one inch and three-fourths in its transverse diameter, and scarcely exceeding an inch in its antero-posterior diameter (Fig. 3). The body and neck of the organ occupy the vagina, and the neck is not more than one inch in diameter, and feels like the pedicle of a polypus. The inversion is recognized as complete, and the organ is no larger than when in its natural position six months after delivery. Introducing a large cylindrical speculum into the vagina, the fundus of the uterus passes readily into its cavity, thus demonstrating the complete involution of the uterus, and bringing distinctly into view the rough mucous membrane of its now outer covering, which bleeds upon the slightest touch with the finger or sound. It is seen to be covered with muco-purulent matter also, and is not susceptible of indentation by pressure with the point of the sound.

Fig. 3.

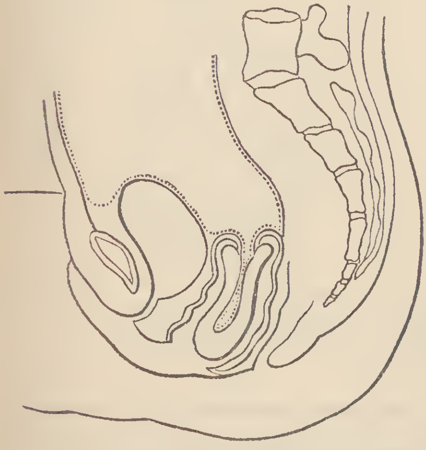

Fig. 4.

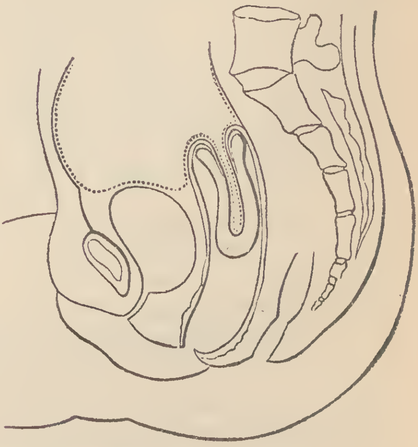

Fig. 3.—Position of the uterus in chronic inversion.
Fig. 4.—Vagina put upon the stretch by pressure upon the fundus.

The bowels having been freely moved by an enema, I proceeded to the operation of reduction in the presence of Drs. Robinson, Reynale, Batten, Dimick, and Mr. J. W. Robinson, medical student. The patient was placed, for the operation, upon an elevated, firm bed, with the hips brought quite to its edge, the knees separated, the feet resting in the laps of Drs. Reynale and Robinson, with directions to each to support a knee and hand of the patient, and prevent

her from moving about. Dr. Batten brought the patient moderately under the influence of chloroform, which was continued throughout the operation, whilst I placed myself upon my knees, between the patient's legs, her pelvis being at a convenient elevation for manipulation. I introduced my right hand completely into the vagina, and firmly grasped the entire body and neck of the uterus. It may here be remarked that the parts were so firmly contracted as to render the introduction of the hand difficult. At the same time that the entire uterine tumor was grasped by the right hand, a large rectal bougie was carried up, and also received into its palm and held firmly in contact with the fundus of the uterus, the hand being sufficiently large to receive both, and keep them in apposition. Continuous, gentle pressure was now made upon the external extremity of the bougie with the left hand, whilst the right compressed the uterine tumor, and kept the upper extremity of the instrument directly upon the fundus, and, with the dorsum of the hand in the concavity of the sacrum, directed the force in the axis of the pelvic cavity, putting the vagina completely upon the stretch (Fig. 4). This pressure was exerted, and this position unintermittingly maintained, although the force was not to such a degree as to endanger laceration of the utero-vaginal connection, until my strength was nearly exhausted from continuity of effort. At length, and when about to relinquish the task, the uterine tumor began to shorten at *its neck*, and the mouth of the organ to push upon the upper surface of the hand. No depression or dimpling of the fundus was at any time perceptible. Ascending more and more rapidly as the neck diminished in length (Fig. 5), the fundus finally passed out of the hand, and was easily pushed by the bougie through the mouth and neck of the organ up to its proper position (Fig. 6).

Fig. 5.

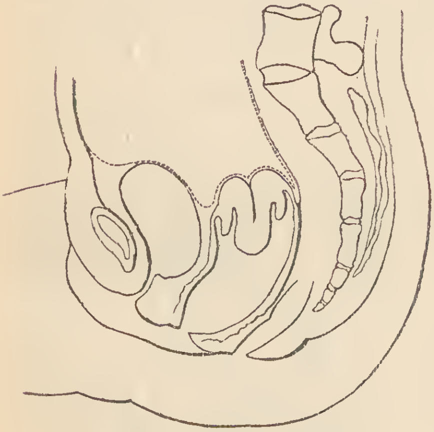

Fig. 6.

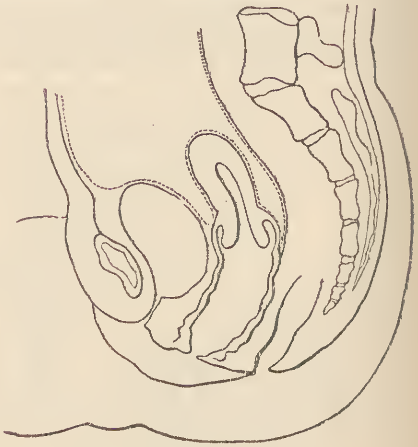

Fig. 5.—Manner in which the os and neck double upon the body.
Fig. 6.—After complete restoration.

In order to verify the restoration, Simpson's sound was introduced alongside of the bougie, and was found to enter a little more than two and one-half inches above the os, which could now be distinctly felt. The large speculum, already referred to, was now slipped up around the bougie, when the os was brought distinctly into view, surrounding also the bougie. The sound was again carried through the os to the fundus, through the speculum, and all the medical gentlemen present saw that it passed easily beyond the mouth, to the shoulder of the sound, and could not, without force, be carried further. Thus was demonstrated not only the reduction of the uterus, but that the organ was accurately measured, and found scarcely, if at all, enlarged. The speculum and sound were now withdrawn, the patient carefully removed to the bed,

and the bougie retained in place by the hand, to prevent reinversion. Meanwhile, stimulants were given to sustain the patient, and ergot in such doses as were deemed likely to excite the tonic contraction of the uterus. The patient soon recovered from the effects of the chloroform, and expressed herself as feeling quite as comfortable as before the operation from which she had suffered but little. The discharge of blood was slight, and, when the effects of the chloroform had passed off, and she had taken a little brandy and water, she expressed herself as feeling comfortable. Pulse not sensibly changed in quality, and numbering the same as before the operation.

Drs. Robinson and Batten remained with the patient during the succeeding night, alternately maintaining the bougie in the uterus, supporting it gently, and rendering such other attention as the patient required. Continuing the pressure upon the fundus of the uterus was perhaps unnecessary, but it was thought safe not to withdraw the bougie until the next day.[1]

March 13, Dr. Robinson wrote: "The patient is quite comfortable; pulse 108. Free from pain. Withdrew the bougie this morning, and found the os uteri embracing it pretty firmly." Tonics with nutritious diet were continued, and quietude in the horizontal position enjoined. On the 15th, he wrote: "The patient is quite comfortable this morning. Made a digital examination, and found the uterus perfectly *in situ*, and mouth well contracted. Has some appetite. Pulse 100." March 23, he again wrote: "She is improving; has been much annoyed by neuralgia and sickness of stomach, but both are giving way, as is the leucorrhœal discharge. The treatment has been sustaining (porter, wine, quinine, iron, etc.), with nutritious diet." In conclusion, Dr. R. adds: "She will get well, and I feel gratified in the success of the effort of restoration, not only on account of the patient being relieved of a loathsome malady, but also that I have been instrumental in contributing to the professional reputation of one for whom I feel a deep friendship, as your success in this case will relieve obstetrical surgery from the opprobrium which has hitherto been attached to it in cases of chronic inversion of the uterus." In reply to a letter of inquiry from me, Dr. Robinson wrote, April 22: "I visited her yesterday, and found her very cheerful and able to sit at the table and take tea with us. Her final recovery is now beyond all doubt. In short, the operation has been as successful as its most sanguine friends could desire. Her convalescence has been protracted; slow, perhaps; but when we take into account the great prostration from the long continuance of the malady, and the exhausting hemorrhages and leucorrhœal discharges to which she had been subjected, the only wonder is that she has recovered at all." This patient, I am informed, nearly twenty years after reduction (September, 1876), is quite well, and able to attend to her household duties.

Case II.[2]—In July, 1872, Dr. George T. Hough, a very intelligent practitioner in New Bedford, Mass., wrote me to know "if I could be induced to come there and operate upon a case of chronic inversion of the uterus which had lately come into his hands." After long efforts to persuade the incredulous sufferer and her friends of the feasibility of making an effort for her relief, I was at length invited by him to visit her on the 15th of May, 1873. In passing through Boston on my way to New Bedford, I called upon Dr. George H. Bixby, the celebrated gynæcologist of that city, and invited him to accompany me. Dr. Bixby was present at the operation, rendered valuable assistance, and furnished the following report to the American Journal of Obstetrics, which I take the liberty of transcribing with many thanks, not only for this report of the case, but for his many courtesies.

Mrs. H., aged 35, native of New Bedford, first menstruated during her thirteenth year. She married at fourteen, and has given birth as follows: the

[1] In all subsequent cases the bougie has been withdrawn immediately after restoration, as there is little or no danger of spontaneous reinversion while the patient is kept quiet and in the horizontal position.

[2] Vide Transactions of the New York State Medical Society, 1874.

first, fourteen years after marriage; the second, eighteen months after the first. She was attended in her last confinement, more than six years ago, by an irregular practitioner. After the delivery of the child, the medical attendant left the patient for two hours, and on his return proceeded to remove the placenta in a very rough and hurried manner. For three weeks convalescence proceeded as usual. She was then taken with profuse hemorrhage. The latter continued in varying quantities and intervals for several weeks, when the family physician was called. Upon examination, he diagnosticated uterine polypus, and a surgeon was summoned to remove it. Accepting and confirming the opinion of the attending physician, the operation was immediately undertaken. The wire of the *écraseur* was with some difficulty applied about the pedicle, but upon making traction it parted. Upon close inspection, after the accident, it was ascertained that the case was one of uterine inversion, originally partial, but rendered complete by the previous manipulation. Nothing further was done at this time.

June, 1872, Dr. George T. Hough, of New Bedford, was called. He found the patient confined to her sofa, where she had been almost continuously since her last confinement. She was thin and chlorotic; menstruation had been regular as to time, but profuse. She suffered, in the intervals, from frequent attacks of hemorrhage, which were provoked by exertions as slight as walking across the room. Frequently slight hemorrhages through the entire interval of menstruation; at other times there was a complete absence of the same. A vaginal examination revealed the following: External genitals normal; within the vagina, a round, regular, conical body, more or less immovable, and constricted at its superior extremity. Upon the application of the usual diagnostic signs, Dr. Hough pronounced the case one of chronic inversion of the uterus. Not feeling quite sure of his diagnosis, Dr. Johnson, of New Bedford, was called in consultation. Dr. Hough's opinion was confirmed by Dr. J. In June, 1872, Dr. Hough consulted Prof. James P. White, of Buffalo, by letter, and subsequently Dr. White was called to see the case.

On the sixteenth of May, 1873, an examination was undertaken by Dr. White, in the presence and with the assistance of the following gentlemen: Dr. Mason, of Norwich, Ct., Professor of Physiology in the Buffalo Medical College, Drs. Hough, Johnson, Hooper, Vermeyne, and Hayes, of New Bedford, and Dr. Bixby, of Boston. Artificial teeth removed and urine drawn; etherization commenced by Prof. Mason. When completely anæsthetized, the patient was placed upon her back across the bed with her pelvis near one side, in a favorable position to allow the lower extremities to be flexed and rest in the laps of two seated assistants. By palpation the uterine tumor in the suprapubic region was found wanting. The excessive emaciation of the patient rendered this point easily demonstrable. By the vagina, the finger came in contact with a smooth, round, cone-shaped body, more or less movable, and constricted at its upper extremity. By the sound, a complete *cul-de-sac* was found encircling the entire constricted portion. By recto-vesical exploration, no interposing tumor was found, and the finger in the rectum was separated merely by the rectal and vesical walls from the sound in the bladder. The case having been clearly recognized as one of chronic inversion of the uterus, the operation of reduction was undertaken as follows: Prof. White assumed the kneeling posture before the patient, and between the two seated assistants. The left hand, well-lubricated, was carefully introduced into the vagina, and the fingers slowly insinuated under and about the mass. While the latter was sustained by the palm of the hand, the constricted portion was embraced by the thumb and finger from opposing sides. With the right hand, Dr. White's "egg-beater, uterine repositor," was introduced into the vagina, its concave extremity placed against the fundus or cone of the tumor, and its spring-end against the chest of the operator. This done, the right hand. now free, was employed for making counter-pressure above the pubes, or for any other desired purpose. Gentle but unyielding

pressure, rendered equable and manageable by the action of the spring, was continued without any variation for thirty minutes, little more force being exerted than that required to compress the spring. Thirty minutes after the commencement of the operation, patient in good condition; hemorrhage insignificant; tumor in vagina still firm; constriction unyielding. One hour from commencement of the operation, hemorrhage insignificant; tumor more soft; a tendency to collapse, manifested by retarded respiration and pulse, was combated by the injection of an ounce of clear brandy into the rectum, to which the heart's action promptly responded. The use of the "egg-beater repositor" was now continued, its action varied by a slow to-and-fro motion of the body upon the spring. At one and a half hours, the patient continued to bear the operation well; hemorrhage insignificant; pulse somewhat accelerated; tumor more soft and compressible; a large-sized, gum-elastic, rectal bougie was substituted for the "egg-beater." At two hours and ten minutes, under the pressure of the bougie and manipulation with the fingers, the constriction suddenly relaxed, and the organ assumed its normal position. The patient rallied from the anæsthesia in less than a quarter of an hour. Reaction took place slowly. Notwithstanding this prolonged manipulation, neither the vagina nor the perineum was in any way injured.

Dr. Hough thus writes in regard to the subsequent condition of the patient: The day after the operation there were symptoms of metritis, which rapidly disappeared under appropriate treatment. There were no bad symptoms following the operation, but two weeks after she suffered from a slight attack of pneumonia from exposure to a draft of cold air at night. One month after the operation: She has sat up, has a good appetite, sleeps well, and gains strength daily; vaginal examination reveals the uterus in a normal position. Some months afterwards, desiring to know the condition of the patient, I addressed a note of inquiry to Dr. Hough, to which the following reply was received:—

New Bedford, Jan. 16, 1874.

My Dear Dr. White:—At your request I visited Mrs. H. yesterday. She says, "Tell the Doctor that I am perfectly well in every respect," and she seems so. Upon inquiry, I find all the functions normal; menstruation perfectly regular, lasting two days; scanty, if anything. She has lost her chloro-anæmic look, and has a good color. Eats and sleeps well, and in fact is well. Very respectfully yours. Geo. T. Hough.

Case III.—In the winter of 1871–2, I received a letter from Dr. O. C. Strong, of Colden, informing me that there was in his neighborhood a case of inversion of more than twenty years' duration. The Doctor had been called in to prescribe for the patient during one of the attacks of flowing from which she had suffered ever since the birth of her child, now twenty years old. Not content with the assertion that she was "bleeding to death," and seeing her exsanguine and feeble condition, the Doctor resolved, if possible, to ascertain the cause of the hemorrhage, before undertaking to prescribe a remedy. Upon instituting a careful digital examination, he recognized what no one who had preceded him in the treatment had ever suspected—complete inversion of the uterus. He soon after wrote me on the subject, asking whether I would be willing to undertake its reduction, etc. Considerable time elapsed before the patient could be made to believe that there was any hope of her relief from a malady which had prostrated her for more than twenty years. At length, through the persuasion of her physician, Dr. Strong, she was induced to invite me to undertake its reduction. The case was reported by A. T. Livingston, M.D., assistant physician in the New York State Lunatic Asylum, in Utica, and from his notes I make the following extracts:—[1]

The history of the patient, prior to the time of the operation, has been obtained principally from a thesis presented to the faculty of the Buffalo Medical College, in February, 1871, by Dr. O. C. Strong, of Colden, N. Y. Mrs.

[1] Buffalo Medical Journal, August, 1872.

A. D., then aged twenty-four, and residing in Buffalo, gave birth to a female child, July 15, 1850. The midwife who attended her in her confinement, experienced some difficulty in the removal of the placenta, but finally succeeded in *pulling it away*. This act was followed by so much hemorrhage as nearly to destroy the woman's life. From this time until the day of the operation she suffered a continual loss of blood, which twice a month amounted to flooding. She consulted various physicians in relation to her condition, but received no benefit from any of them. This is not surprising when we are told that, until Dr. Strong was called to see her in 1870, no physician had ever proposed to make an examination per vaginam with the view of determining the cause of the hemorrhage.

March 2, 1870, Dr. Strong was called to attend Mrs. D. He found her lying upon a bed, about which were evidences in abundance of the terrible flooding which had just occurred. Upon making a digital examination, he discovered a tumor about the size and shape of a small pear, occupying the vagina, which, after a careful specular examination, he diagnosed as an inverted uterus. Dr. S. informed his patient that he considered that her condition permitted the use only of palliative measures, and advised the use of tonics and local astringents. Afterwards, learning of Dr. White's previous, successful operations for chronic inversion of the uterus, a correspondence arose between that gentleman and himself, with reference to the case of Mrs. D., which resulted in an invitation to Dr. White to visit the patient, and, if upon examination he should think it advisable, to attempt the reduction of her uterus.

June 23, 1872, Prof. White, with Profs. Julius F. Miner and M. G. Potter, Drs. Geo. N. Burwell, W. C. Phelps, and the writer, whom he kindly invited to accompany him, proceeded to the residence of the patient in the town of Colden, N. Y. She was found to be feeble and very anæmic, and slight hemorrhage from the tumor was then occurring. Prof. Potter, who was requested to take charge of the anæsthetic, administered some chloroform to the patient, and the tumor was then examined by several of the gentlemen present. It resembled in size and shape an ordinary hen's egg, and was suspended in the vagina by a long, narrow pedicle continuous with its upper and smaller extremity. This appearance, particularly the small and elongated cervix, led some who examined it to doubt its being a uterus at all, and to consider it rather a polypoid growth. But a probe could not be passed along the pedicle into the os, as might have been done had the tumor been a polypus, nor could the uterus be detected by palpation over the abdomen. A uterine sound passed into the bladder could be felt by the finger in the rectum above the tumor, and by the hand placed over the hypogastrium; also the finger, passed up the rectum, came in contact with the anterior abdominal wall as felt by the other hand. All these diagnostic means proved the absence of the uterus from the situation which it ordinarily occupies. By these negative proofs, Dr. White was entirely convinced that the tumor was the inverted uterus, and he therefore proceeded to attempt the reposition of the same in the presence of the above-named gentlemen, and of Drs. Strong, of Colden, G. H. Lapham, of Aurora, and Davis, of Boston. Dr. Potter had produced anæsthesia by chloroform, which he now exchanged for ether, with which he kept the patient anæsthetized during the operation. Dr. White assumed a kneeling posture in front and between the legs of the patient, who had been placed upon the side of the bed with her hips projecting a little beyond its edge, and her feet resting in the laps of Drs. Miner and Phelps, who sat on either side of Dr. White, each supporting a knee and holding a hand of the patient. Dr. White then introduced his right hand into the vagina, and began manipulating the tumor. This manipulation consisted in compressing the uterus, which relieved its congestion and rendered it more pliable, and in making gentle pressure in the line of the axis of the pelvis by the use of the uterine repositor. After continuing this a short time the doctor brought the tumor down to view, when a glance sufficed to assure the doubting of its true nature. By the pressure which had been exerted the neck had been

shortened and dilated, the body and fundus reduced in size, the superior angles (now inferior) were distinctly seen, and altogether the tumor then presented the normal outline of a uterus of small size. The repositor was again introduced, and a pressure of eight or ten pounds exerted by it, and, at the same time, compression was made by the hand within the vagina upon the portion of the uterus protruding beyond the os, the same hand also retaining the fundus uteri and the repositor in coaptation, whilst the left hand was employed in pressing above the pubes or through the rectum. When, in this manner, the cervix had been made to embrace the fundus, the uterine repositor was substituted by a large rectal bougie, with which pressure was continued until the close of the operation.

At the end of an hour and fourteen minutes, Dr. White was obliged to discontinue his efforts on account of the benumbed condition of his intra-vaginal hand, caused by the pressure upon it of the narrow and unyielding vagina. The fundus was at this time within the cervix and above the os, and the doctor considered the reduction substantially accomplished. He requested Dr. Miner to continue the manipulation, which he did, and in sixteen minutes, or just one hour and a half from the beginning of the operation, Dr. Miner enjoyed the satisfaction of announcing that the uterus, which for twenty-two years had been completely inverted, was now as completely reposited. Two hours after the operation, when we left her, the patient was quite as comfortable as could have been anticipated. An opiate was administered, and directions were given the attendants to keep her perfectly quiet for at least a fortnight. By letter dated June 27, Dr. Strong reports: "Mrs. D. doing better than we had dared to expect." July 2, Dr. Strong writes: "Our patient is doing well, and nothing has yet interfered with her progress toward recovery." July 19. "Since the operation upon Mrs. D., nothing has transpired to mar the beauty of the result. The pulse has at no time exceeded ninety per minute." At this time a careful examination "shows the uterus occupying its normal position, the intra-vaginal portion of the neck presenting the ordinary appearances of mild cervicitis. The patient is now about upon her feet some portion of her time, and everything points to a rapid, and I think, perfect cure. She has had no sanguineous discharge since the operation."

On the 23d of August, two months after the operation, the following letter was received :—

My Dear Doctor :—Allow me to congratulate you on the perfect success of your operation upon Mrs. D. I have delayed writing thus long that I might not be required to retract any statements made in regard to the success of the operation. The most sanguine could not have expected so good a result. She now does her own work, goes on foot to the neighbors', rides ten miles and returns over the hills, and in fine now seems competent to perform her part in life. At the expiration of four weeks from the operation, she had a regular menstrual discharge, which seemed perfectly normal both in regard to amount and character. Your obedient servant,

O. C. Strong.

In order to ascertain her subsequent condition, I addressed a note of inquiry to the doctor, and received the following reply :—

Colden, Jan. 20, 1874.

My Dear Doctor :—Your note of inquiry is received. In reply permit me to say that Mrs. D. is in the enjoyment of good health; that her menses are regular; that in her present appearance one can see nothing to tell the tale of those twenty-two long years of suffering; nothing that speaks of terrible floodings; and, in fine, nothing to show that she ever possessed an inverted uterus. Very truly yours,

O. C. Strong.

It would seem an unnecessary expenditure of the time of this learned body to detail the remaining nine cases. Those related fairly illustrate the state of the organ at the different periods of the accident, and the mode of operating for its restoration. The result has been, in all the cases encountered, restoration by manipulation on the first trial, and as is believed without serious injury to the tissues, thus confirming the conviction that all cases are curable, irrespective of their duration.

CASE OF RETROVERSION OF THE GRAVID UTERUS; TREATMENT BY PUNCTURE; RECOVERY.

BY

THOMAS F. ROCHESTER, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

On December 17, 1874, three children, the eldest ten years of age, were attacked with a severe form of scarlet fever. Their mother, with characteristic maternal devotion, was almost their only nurse, although at the time of their seizure she had commenced the second month of her fifth pregnancy. She was on her feet a great deal, and very frequently lifted and bathed the children, although herself of slight and delicate frame. To this she ascribed the unusual pressure and bearing down experienced in the recto-vaginal region, such as she had never felt in her previous pregnancies.

A little after midnight on March 17, 1875, her husband informed me that his wife feared a miscarriage, as she was in great pain, and flowing profusely. Visiting her immediately, and making a digital examination, I found the vagina filled with an elastic, globular mass, as large as the fœtal head at full term. Nothing like an os uteri could be found. The sub-pubic space was tightly filled, as was also the perineal; it was impossible, by rectal exploration, to pass the finger above the lower segment of the tumor. The hemorrhage was free, and was found to emanate entirely from the urethra. A catheter was introduced with considerable difficulty, the instrument taking a backward and downward direction, and serving for the evacuation of about six ounces of very bloody urine. So impacted was the vagina, and so strong was the pressure upon the rectum, that it was impossible to make the vesico-rectal exploration by the catheter and finger.

The case was presumptively one of retroversion, or rather of complete eversion of the pregnant uterus, at or exceeding four months. The condition was so grave that the attendance of my colleague, Prof. James P. White, was obtained in consultation as soon as possible. He made a most critical examination, and was, like myself, unable to find the os uteri. We concurred in the opinion that it was either complete eversion or an immense hæmatocele, and that, in the former event, any attempt at restoration was out of the question on account of the strong pressure and great size of the tumor, and that the attempt would probably be followed by metritis or rupture, or both.

It was resolved to puncture the mass with a small exploring trocar, and the tumor was accordingly pierced at its most depending portion, when about four ounces of clear, straw-colored fluid passed through the canula. There was no blood, the fluid being evidently liquor amnii. Half a grain of morphia was administered, and the patient was left to obtain a few hours of much needed rest. At 5 P. M. the patient was very comfortable. She was now placed in the knee-face position, and an endeavor was made to lift the fundus; but this could not be done. The

bloody urine was still passed, but not as frequently or as painfully as before. The morphia was repeated.

On the morning of the 19th, slight labor-pains set in, and increased in force and frequency very gradually. With each pain the mass sensibly contracted, and the everted fundus was lifted a little toward the rectum. Shortly after midnight, on the 19th, the pains became forcing, and, at 3 A.M., a flattened sphere, the fœtal head, emerged under the pubic arch. At 4 A. M. a male fœtus, nine inches long, was expelled, and very soon after was followed by the placenta and membranes. The intra-vaginal tumor was now diminished about one-half in size, but still retained its completely capsized position, and it was still impossible to feel the os uteri. It was not thought proper to make any immediate effort towards restoration. At 5 P. M. eight ounces of urine, slightly tinged with blood, were removed by the catheter, and during the two following days the urine was drawn, morning and evening, constantly improving in appearance.

On the 22d, copious alvine evacuations followed a soap-suds enema, and on the evening of the same day the os uteri was distinctly felt under the pubic arch, and the fundus had receded to the sacral hollow. From this time forward the catheter was not used. On the 22d, there was an abundant lacteal secretion, which disappeared spontaneously in about ten days. The patient was instructed to lie upon her face and sides, and to avoid straining at stool. By April 5, she was apparently perfectly well, the lochia had ceased, and there was no vesical or rectal irritation. The uterus became gradually reduced in size, but still retained its retroverted position, and it was still thought safest to defer attempts to replace it. The patient was in fact too well to be disturbed, and had manifested no serious symptoms, except local ones, during the severe ordeal through which she had passed. She was always bright and hopeful, suffered little pain, and had at no time any febrile movement; her pulse was only accelerated to 100 for the two days preceding the expulsion of the fœtus. She was instructed to use warm vaginal and rectal enemata daily, to maintain the recumbent or semi-recumbent position, and to await the proper time for interference, which she very patiently did.

On May 1, her menstrual period came on, and lasted five days. On May 13, Simpson's sound was passed in, to the depth of three inches, and the uterus was by its aid placed in the proper position, from which, however, it fell back within a day or two. This operation was repeated, once a week, until the second period returned, which was on May 31. On June 10, the uterus was placed in position; on the 19th, it had receded again, was restored with the sound, and was now retained in position with a cradle-shaped, hard-rubber pessary. This was worn with entire comfort for six months, and was then removed. The uterus has since retained its proper position. The patient is apparently perfectly well, but has not been again pregnant.[1]

Remarks.—This case has been presented, certainly not for its novelty, but to illustrate the successful result of a method of treatment. When

[1] June 11, 1877. The patient is again three months advanced in pregnancy. She consulted me at the end of the second month, when the uterus was again found retroverted. It was replaced by the repositor, but it was found necessary to retain it *in situ* by a pessary, and the three-winged instrument of Thomas was employed successfully, after failure with the cradle-shaped one previously worn. At the present date, gestation is progressing favorably.

we consider the number of fatal cases on record, and when we further consider the serious injury that has frequently resulted to both bladder and womb, either from entire neglect or from repeated and protracted attempts at restoration, and when we remember that in the greater proportion of cases of retroversion of the gravid uterus, even if the organ is replaced by posture and manipulation, the operation is almost always followed by abortion and metritis, may not the procedure which has been described be more safe than the treatment usually adopted? I do not wish to be understood as advocating puncture or tapping of the womb, through its walls, in preference to separation or rupture of the membranes through the os uteri, when this is accessible; but only when, as in the case reported, the os cannot be reached.

ON THE COMPARATIVE VALUE OF CAUSTICS AND ASTRINGENTS IN THE TREATMENT OF DISEASES OF THE CONJUNCTIVA, AND ON THE BEST MODE OF APPLYING THESE REMEDIES.

BY
HENRY W. WILLIAMS, A.M., M.D.,
PROFESSOR OF OPHTHALMOLOGY IN HARVARD UNIVERSITY.

The conjunctiva, one of the least in extent, but one of the most important, of the mucous membranes, is the seat of affections singularly various in form and degree—from the simplest transient congestion to the most violent inflammatory processes and most persistent structural alterations. On the treatment of these depends, often, the preservation or the loss of the most important of our special senses, and the fairest prospects in life may be blighted by either mismanagement or neglect.

In preparing the paper which I now offer to the Section on Ophthalmology, I have avoided a recapitulation of every theory as to pathology and treatment, and offer simply a few practical suggestions, with no wish to unduly depreciate the value of other means and methods than those for which I express a preference. Skilful men will know how to use various instrumentalities to attain good results. Nevertheless, it is desirable, and important, to discriminate among the agencies at our command, and to select such as practically prove best adapted to the cure, *tuto, cito, et jucunde*, of the diseases which we are considering.

A considerable number of conjunctival affections require little or no treatment, and are injured rather than benefited by the use of other than the mildest remedies. The hyperæmia caused by the presence of a foreign body subsides upon its removal; the injection depending on astigmatism, or other defects of refraction, disappears after the selection of suitable eye-glasses; the sub-conjunctival ecchymosis following a blow, or the rupture of a small bloodvessel, is re-absorbed, perhaps quite as rapidly, without our interference. If, in these cases, we prescribe a lotion

or a collyrium, it should be quite unirritating. So also in traumatic injuries of a simple character, and after operations for strabismus or pterygium, the healing processes go on without assistance from applied remedies. Chemical injuries, because of their graver nature and the degree in which the cornea may be involved, oftener require our aid; but even here, emollients and sedatives rather than active stimulants are most useful.

With the above-named exceptions, and apart from certain complications hereafter to be considered, diseases of the conjunctiva may be divided into two classes requiring essentially different management. The first includes a comparatively simple, limited, and benign, though sometimes chronic, affection; the second embraces several conditions of general and often severe conjunctival inflammation. The prominent feature of the first class is the development of small elevations or papulæ, one or several in number, usually situated at or near the border of the cornea, though they may form elsewhere on the ocular conjunctiva. The summits of these may be whitish, as if containing a minute quantity of pus; more frequently they are red; and they may vary in size, but are commonly about that of a hemp-seed. Usually a fasciculus of vessels runs to each of these papulæ; but there is no general injection of the conjunctiva, except as far as may be the result of friction of the papulæ against the inner surface of the lid. Children are the most frequent subjects of this disease.

The tendency of this affection is towards a disappearance of the symptoms at the end of a few days, even when no treatment is employed. Therefore, no active remedies of caustic or astringent nature are needed, and they tend to delay rather than hasten the recovery. Calomel or other insufflations are similarly useless. All annoying remedies are moreover objectionable on account of the age of the majority of the patients. Simple lotions, cold or tepid, with water, or milk and water, may be used. Two or three times a day, a few drops of a solution of ten grains of borax in an ounce of water, or of camphor water, may be dropped into the eye from a teaspoon or a drop-tube. This usually proves a soothing and refreshing collyrium, grateful rather than painful to the patient, and appears to have a sufficiently astringent and stimulating effect to promote absorption of the papulæ. Although the ordinary duration of these small pimples rarely exceeds ten days, it is not uncommon, whatever treatment has been employed, to find successive crops of them, at intervals of a week or two. This disposition seems to be best obviated by continuing the use of the borax collyrium, once or twice a day, for some time after recovery, so as to modify the condition of the conjunctiva. Where the papulæ are slow in disappearing, the application of a crayon of alum, once in a day or two, to the inner surface of the lower lid, is often useful and is nearly painless. The astringent reaches the affected spot as the lid returns to its place, and seems sometimes to excite a more rapid resolution. The papulæ themselves should never be directly touched with caustic or astringent crayons or solutions.

Very rarely, the disease takes a more chronic form, the papulæ being as large or larger than a split pea, and sometimes umbilicated at the centre. Though persisting longer, and for a time intractable to treatment, the prognosis is always favorable. Tonic general remedies, and sometimes change of air, are useful adjuvants to the mild local applications. Solutions of atropia have of late been too much in vogue in the treatment of this form of disease. Though far less dangerous than the strong caustic remedies which were formerly indiscriminately employed, yet an

unnecessary resort to them has grave disadvantages. In cases of corneal ulceration they may be of much service, in lessening the irritability and photophobia; whilst in these less serious conjunctival affections their action upon the pupil does but increase the intolerance of light, and, by exciting strong contractions of the lids, creates a disposition to corneal ulceration as an effect of friction.

The second class of conjunctival affections comprises catarrhal conjunctivitis in its acute and chronic forms, trachoma, purulent and gonorrhœal conjunctivitis, ophthalmia of new-born children, and diphtheritic conjunctivitis; each of which conditions has an importance claiming distinct consideration.

When the conjunctiva becomes affected from exposure to cold, dust, or other simple causes of irritation, the first symptom is injection with an increased flow of tears—soon followed by a velvety thickening of the palpebral conjunctiva and a slight mucous secretion. These phenomena may occur so suddenly that the patient feels sure that something has been blown into his eye; but the scarlet, velvety appearance of the lining of the lids, as distinguished from the mere vascular hyperæmia excited by the presence of a foreign body, renders the differential diagnosis sufficiently easy. At this stage, caustics and strong astringents are alike to be avoided, or used with great reserve. Frequent bathing with cold or tepid water according to the sensations of the patient, with applications, four or five times a day, of a few drops of a solution of ten grains of borax in an ounce of camphor-water, or of five grains of alum or one grain of sulphate of zinc in an ounce of water or rose-water, will generally cut short even a sharp attack and remove the symptoms within three or four days. Occasionally this form of conjunctivitis is epidemic, large numbers of persons being attacked within a short time. Similar, with perhaps somewhat more active, means, are here called for; one or two touches inside the upper lid with a crayon of alum, or, very rarely, a single light touch with a crayon of sulphate of copper, acting as useful auxiliaries in arresting the symptoms in an early stage. If neglected or if too actively treated, the thickened conjunctiva assumes a more or less granulated aspect, and a chronic phase of disease is established which requires more active measures. The lining of the lids, especially the upper, from hypertrophy of the conjunctival follicles, now resembles in appearance the surface of a raspberry, and the sub-conjunctival tissues become so infiltrated that the lid-movements are difficult. The secretions are greatly augmented, causing abundant flow in the daytime, and agglutination of the lids at night. Here, as in another affection next to be described, the mild remedies, sufficient for the lesser degrees of inflammation, are of little avail. Caustics or astringents, of considerable potency, seem to be our only resource.

Trachoma differs widely, pathologically, from catarrhal conjunctivitis, though often coexistent with and complicating it. It consists essentially in a neo-plastic formation; at first in small, oval-shaped, semi-transparent masses, resembling grains of tapioca; and sometimes increasing until the conjunctiva, with its subjacent textures, is largely transformed into a dense, nearly structureless mass, which, as recovery takes place, is not replaced by normal tissue, but is followed by contraction of the conjunctiva and incurvation of the tarsal cartilage. Here, the prognosis is less favorable, the recovery slower, and the danger of secondary lesions of the cornea much greater than in the catarrhal form of conjunctivitis.

But the local treatment of the two affections has much similarity, and may be either caustic or astringent, or both.

Nitrate of silver is the caustic most relied on in the treatment of conjunctival affections, though other means have from time to time been tested and enjoyed ephemeral reputation. The methods of using it, and the means employed to limit its effects, vary with different ophthalmologists. The crayon of pure nitrate and the nearly saturated solution, formerly much used, are now rarely employed, but have given place to the lapis mitigatus, as it is termed, in which one part of nitrate of silver and two parts of nitrate of potassium—or two parts of silver and one of potassium—are fused together; or to solutions of nitrate of silver of from ten to forty or more grains to an ounce of water. The caustic is applied, in most cases, to the surface of the everted, upper lid, more or less lightly or extensively, the stick of lapis mitigatus being preferred by some, the solution of nitrate of silver by other authorities. When thought advisable, the action of these substances is limited by the immediate application of a neutralizing solution of salt and water, or pure water, or both of these, to the cauterized surface. The frequency of the repetition also varies greatly, in the practice of different individuals: once, twice, or thrice a week, daily, or oftener, according to the intensity of the symptoms or the preferences of the practitioner. Moreover, some rely wholly on this means; others employ auxiliary treatment. Theories as to therapeutic effect also vary with different observers, some seeking to destroy the apices of the granulations, while others, deprecating such an effect, use the caustic with more reserve, and, virtually, as a strong stimulant only.

In the class of astringents employed as topical applications by the physician himself, may be named, crayons of sulphate of copper; the lapis divinus, composed of equal parts of sulphate of copper, alum, and nitrate of potassium moulded into sticks; crayons of alum; and strong solutions of tannin in glycerine. Of these, the crayon of sulphate of copper forms the best type; as combining the several qualities of convenience, efficiency, and safety. The alum crayon has an excellent effect in mild forms of conjunctivitis, but is inefficient in the severer and chronic affections. The lapis divinus seems less reliable than the crayon of pure sulphate of copper. Tannin and other vegetable astringents, from which theoretically we should expect so much, have always proved, in my hands, in whatever proportion or combination, inferior to the mineral astringents; whether as a means of energetic action upon the conjunctiva, or as used in collyria to produce milder continuous effects.

The sulphate of copper cannot be fused in moulds, like nitrate of silver and lapis divinus, but the crayons have to be shaped from crystals of the substance. Unfortunately, these are generally much broken at the laboratories in packing for the market, but if good crystals can be found it is easy to cut from them crayons of convenient size. The harder parts of the crystal, free from pores or water of crystallization, are to be chosen. Nothing would be needed to obtain ample supplies of the crystals, or of crayons already shaped from them, but the knowledge that there was a demand for them, as they are easily made from crystals obtainable at the laboratories, and they require no care in keeping, being little changed by exposure to air or light. A single crayon lasts a long time, and may be used, like a silver probe or a bistoury, for successive cases, care being of course taken to wipe the crayon after every application. The crayon of sulphate of copper should be applied, as a rule, rather lightly to the

conjunctiva of the everted upper lid; this lid, in which the circulation is more readily congested, being usually more diseased than the lower lid. It is rarely necessary to touch both lids, as a portion of the remedy, dissolved by the moist surface over which it is passed, is carried by the movements of the lids to every part of the conjunctiva. In sluggish cases the crayon may be applied more heavily, or may be more frequently repeated.

Used as above described, the crayon of sulphate of copper does not act on the conjunctiva as a caustic, but only as an energetic astringent and stimulant. In the more acute cases, the pain, after the first or even after several applications, may continue for some time; though it is much less severe and enduring than when caustic has been used. Bathing the eye with water shortens and mitigates the smarting. While the pain is much prolonged, the crayon should be used lightly and perhaps less frequently than after the eye has become more tolerant of the remedy. The touch may then be harder, and may be repeated daily or less often, according to the judgment of the physician. When the crayon is well borne, cases often improve the more rapidly according to the greater frequency of its application; this being especially observed in many chronic cases, trachomatous, and other.

That many cases of muco-purulent or trachomatous forms of conjunctivitis may be successfully treated with nitrate of silver, pure or combined, does not admit of a doubt. Its action requires to be carefully watched, and good judgment must be exercised in determining the frequency and severity of its application, and in neutralizing at once any excess of the caustic. More benefit is obtained from its moderate than from its too free use. Care must also be taken not to continue it too long, as not infrequent instances have occurred in which the conjunctiva has acquired an indelible, olive stain, or even become quite black, from the prolonged instillation of a moderately strong solution. If employed, caustics should not be solely relied on, but should be supplemented by other milder remedies of stimulating or astringent nature, which may be more or less frequently applied by the patient or his friends.

The use of caustic as an application to the eye is not without its dangers. Its active properties render it a destructive agent in unskilful hands; and it sometimes disappoints even the most experienced oculist. The application of the crayon of sulphate of copper involves no such consequences as are inseparable from the use of nitrate of silver. If it happens to be injudiciously employed, no special harm is done and no immediately destructive effects ensue from its use. It is, therefore, a far safer agent in inexperienced hands.

It remains to consider whether the general results of treatment will be more successful under the one or the other plan.

My own experience, which has included careful personal observation of the practice of nearly every European oculist who has had celebrity within the last thirty years, has satisfied me that better and quicker results, with far less danger and suffering, are obtainable from the use of astringents than from the use of caustics. Many years since, I made comparative tests of the value of these two classes of remedies in severe and chronic forms of conjunctivitis, on a large number of patients. Selecting cases where both eyes were equally diseased, I treated all the right eyes with nitrate of silver, and all the left eyes with sulphate of copper. Of course, no differences of constitution could influence the effect produced, as might, perhaps, have been alleged had merely a certain number of patients

been chosen for each mode of treatment and the same remedy used in both their eyes. The uniform result was a more rapid gain in the eyes treated with the crayon of sulphate of copper. Some of the eyes treated with nitrate of silver went on tolerably well, though slowly; but others did so badly that, after vain attempts to succeed by varying the strength of the caustic applications, I was at last compelled, in order to avert threatened loss of the eyes, to substitute the use of the sulphate of copper, under which they recovered. In no instance was it necessary to abandon the sulphate of copper and resort to another remedy.

A very important adjuvant to treatment, either by caustics or astringents, as applied by the physician himself, consists in combining with these the more or less frequent use, at home, of a milder astringent or stimulating collyrium. Of these, the mineral seem to be superior to the vegetable astringents, as also to the purely stimulating class of collyria, such, for instance, as those containing wine of opium or corrosive sublimate. Many substances have been employed with more or less advantage. Among those most in use may be mentioned solutions of nitrate of silver, sulphate of zinc, acetate of zinc, sulphate of copper, sulphate of cadmium, alum, and borax. Of these, the sulphate of zinc seems by far the best for the forms of conjunctivitis which we are considering, as it appears to have a more astringent with less irritant action than either of the other remedies. The silver, copper, and cadmium solutions, are too actively stimulating, with less of astringent effect; the alum and borax are too mild. The sulphate of zinc solutions may vary from half a grain to four grains to the ounce of water or rose-water; and a few drops may be poured into the eye from a teaspoon, a drop tube, or otherwise, two, three, or four times a day. In cold weather the spoon may first be dipped into hot water for a moment, so as to warm the collyrium, if the eye is sensitive as to the temperature of the drops. I have found the sensations of the patient a useful guide in determining the strength of collyrium likely to be of most benefit to him. If a solution of a given strength, say of two or of three grains to the ounce, causes smarting for more than five minutes, it should be diluted one-half, or until it no longer gives more than a few minutes' pain. Thus graduated, the collyrium should be used often enough to keep up a moderate remedial influence.

Acetate of lead, in substance or solution, formerly much in favor even with the profession, and still in common popular use, should *never* be put into the eye. It has no special remedial value to warrant its employment; and whenever the conjunctivitis is, or becomes, complicated with corneal ulceration, great harm is done; the acetate being decomposed, and an indelible deposit formed on the ulcerated surface, causing permanent opacity of the cornea. It is therefore better to erase it from the list of ophthalmic remedies.

More actively virulent forms of conjunctivitis are found under the designations of purulent conjunctivitis, gonorrhœal conjunctivitis, and the conjunctivitis of new-born children. Purulent conjunctivitis, sometimes termed Egyptian Ophthalmia or Ophthalmia of Armies, is marked by far more rapid sequence and violence of symptoms than the catarrhal or trachomatous affections. In pauper asylums, schools, and barracks, it may speedily extend to a large number of persons by direct infection of healthy eyes with the purulent discharge from those which are diseased. This is largely conveyed through the promiscuous use, in such institutions, of articles of toilet, wash-basins, towels, etc.; and is some-

times purposely introduced; the fearful risk of blindness being incurred for the sake of avoiding military or other duty, or of obtaining some hospital privilege. Enormous tumefaction of the conjunctiva and of the entire lid, and copious muco-purulent discharge, characterize this disease. Serous or even phlegmonous chemosis of the subconjunctival cellular tissue often forms a dangerous complication, interfering with the proper nutrition of the cornea; and ulceration of that structure may result from the direct pressure of the swollen lid, or from the continued maceration in the copious purulent secretion.

Gonorrhœal conjunctivitis is even more intense in its symptoms and rapid in its course. Caused by infection with gonorrhœal matter or with the discharge from an already diseased eye, it is more common in men than in females, the fingers being often the medium for conveying the urethral discharge to the eye. One eye only is usually affected at the outset. The frequency of phlegmonous chemosis, and consequent danger to the cornea, is greater than in the simple purulent affection. So rapid is the course of the disease, that an eye may be lost by sloughing of the cornea within twenty-four hours from the moment of infection.

Active cauterization of these forms of conjunctivitis, especially the gonorrhœal, was formerly practised as an abortive treatment, in the hope of substituting a less dangerous traumatic inflammation for the specific infection. This idea has been generally abandoned, and the modern treatment is in all respects milder. As general means, tonics, instead of copious depletion, are in favor; and, as regards local treatment, great importance is to be attached to the frequent use of mild detergents, injected beneath the swollen lids, to remove the abundant purulent secretion. If caustics are used, the applications should be neither too strong nor too frequent, and should be at once neutralized—as otherwise they tend to increase the phlegmonous chemosis and perhaps destroy the cornea. They should not be continued if corneal ulceration has begun. If the crayon of sulphate of copper is applied at all during the active stages of the disease, it should be lightly used; but it is most serviceable in removing the granulations which remain after the active symptoms are abated. The application of cold compresses, constantly renewed, to the lids; frequent removal of the fast accumulating secretions; and the keeping up an influence on the diseased conjunctiva by means of mild astringent collyria, appear to form the most reliable treatment. Solutions of five grains of alum or ten grains of borax to an ounce of water may be injected several times a day, and a solution of half a grain to two grains of sulphate of zinc may be used three or four times in twenty-four hours. The application of a crayon of alum to the inside of the lid, once or twice a day, is sometimes of great apparent benefit, and is safely and easily applied as an auxiliary to the astringent solutions. It is nearly painless, and has little stimulating action as compared with its astringent qualities. It should be used by introducing it beneath the lid without everting it. If the case is seen early, these means are generally effectual; but unfortunately the vitality of the cornea is in many instances already destroyed when the patient first applies for advice, and the prognosis is then unfavorable.

No disease of the eye imposes greater responsibilities upon the general practitioner than ophthalmia neonatorum, the conjunctivitis of new-born children. Occurring within a few days after birth, under circumstances which, in a large proportion of cases, preclude a consultation with any practitioner of special experience, the preservation or loss of sight must

depend on the skill of the family physician. A slight conjunctival injection and tumefaction, with some mucous discharge, is not uncommon in infants, and yields to simple means of cleanliness. But true ophthalmia neonatorum, preceded perhaps only by a slight reddish hue along the skin of the upper lid, becomes within a few hours an intense inflammation. The lids are tumefied, livid, sometimes projecting much beyond the supra-orbital ridge, or even completely everted from the enormous swelling of the conjunctiva. The chemotic infiltration of the cellular tissue beneath the ocular conjunctiva often causes this to overlap the cornea or even to hide it. The secretion is exceedingly abundant. This disease is one of the most destructive, but happily also one of the most manageable, of the affections of the eye. If neglected, or if treated with inert domestic remedies such as injection of breast milk, or with more harmful means such as the application of poultices, the result is too frequently the loss of one or both eyes. Equally baneful consequences follow the use of harsh measures. The great danger attending the use of caustics, in any form, or of very strong astringents, and the *needlessness of resorting to them*, cannot be too strongly insisted on. The symptoms invariably yield to a mild treatment, if reasonably begun and faithfully carried out. If, as is sometimes the case, the cornea has already become more or less cloudy before the attention of the physician is called to the eyes, this furnishes an additional reason for refraining from strong caustic or astringent remedies, which are never well borne when the cornea has become involved.

The first indication is to insure the utmost attention to cleanliness. The copious, muco-purulent secretion should be washed from the eyes every two hours, every hour, or even every half hour if necessary. Should the great tumefaction of the lids prevent their being readily opened so as to permit free discharge of the pus, the nozzle of a small syringe should be passed beneath the swollen upper lid, and an injection thrown in to completely wash out the conjunctival cavity. For this purpose tepid water may be used in the milder cases; in those of more severity a solution of alum, five grains to the ounce, may be alternated with the injections of water. These injections should be repeated hourly or oftener, according to the severity of the case, during the day, and two or three times during the night. They are nearly painless, and the nurse or mother should be taught how to make them. In a few days the discharge lessens and the swelling of the lids diminishes; but the treatment must be kept up, though with less frequency. The physician should not fail to assure himself, by daily inspection, as to whether the cornea retains its normal appearances; and where the swollen condition of the lid prevents a view of the cornea, an elevator should be carefully used to draw up the lid. If the cornea is seen to be even slightly cloudy at its centre, a drop of a solution of sulphate of atropia, two grains to an ounce of water, should be put into the eye twice daily, to lessen the danger of hernia of the iris in case corneal ulceration and perforation should occur. This haziness and ulceration may come on very early in the disease, as a result of the continuous pressure of the lid upon the cornea, or as the effect of its constant immersion in the purulent secretion; but this threatening condition may also supervene at a later stage, and after marked amelioration of the active symptoms; so that the physician, unless on his guard, may lose the battle in the moment of apparent victory.

The use of the nitrate of silver or of lapis mitigatus, is still recom-

mended by some of the continental European oculists; but the milder plan above described has been, for many years, almost exclusively in use at the ophthalmic hospitals of London, and especially at the Moorfields Royal London Ophthalmic Hospital, probably the largest institution in the world for the treatment of eye-diseases, and certainly the most distinguished for the celebrity of its medical staff. In my own experience, success has always attended the mild plan of treatment; and I have seen so many examples of the destructive consequences of harsher methods, that I cannot regard them otherwise than as unnecessary and injudicious.

Two classes of complications of conjunctivitis are worthy of our attention, in their relations to the questions of remedial action which we are considering. In one of these classes the conjunctivitis results from other morbid processes; in the other class the morbid conditions are the consequence of pre-existing conjunctivitis. In the first class, including cases where conjunctivitis appears as a symptom in keratitis, iritis, or in other inflammations of the interior structures of the eye, the conjunctival injection is not to be regarded as a disease, and its treatment, if any, must be subordinate to or modified by that of its primary exciting cause, the removal of which often suffices for the cure of the secondary conjunctival symptoms. In most of these conditions the use of caustics and astringents is contra-indicated. Instead of relieving, they excite yet further congestion of the external membrane, and increase rather than lessen the deeper seated inflammation. Tepid, unirritating lotions, and collyria containing a few grains of borax, may be used as sedatives, if the patient finds them agreeable. Active use of either caustics or astringents is also to be avoided in conjunctivitis accompanying corneal ulceration, or the presence of papules on the epithelial layer of the cornea, in children; as also, especially, in ulcerations of the cornea in adults, occasioned by debility, in old age, or as a sequela of smallpox or other depressing disease.

The second class of complications embraces those conditions resulting from conjunctivitis, usually from its chronic duration, as seen for instance in pannus and secondary keratitis. Here, the attention must primarily be directed to the removal of the original disease, by such remedies as have been already indicated; but we must be careful to make such modifications of treatment as may be required by the secondary symptoms or structural changes, while we avoid the error of regarding these as the essential morbid conditions and directing our treatment solely to them. For example, in the affection styled pannus, where the epithelial layer of the cornea has become so thickened and vascular as to resemble a piece of red flannel, it is useless to attempt to remove this vascularity by division or scarification of the vessels. The abnormal condition of the external layer of the cornea is the result of constant friction by trachomatous or other granulation of the lids, and is to be cured through the removal of these by the patient use of astringents. After the friction has ceased to irritate the corneal surface, the injection and cloudiness gradually fade away. If ulcerative or exudative processes have begun in the cornea itself, caustics are not admissible, but the use of atropia should be combined with the astringent remedies, the continuance of which in moderation is necessary for the removal of the granulations. A certain degree of vascularity is essential to the absorption of the cloudy transformations, and disappears as these fade away.

Some other more exceptional complications should be briefly referred

to. When chronic conjunctivitis accompanies obstruction of the lachrymal passages, mild astringent collyria may be combined with the appropriate means for the removal of this obstruction. When it is coincident with disease of the Meibomian glands or ciliary bulbs, these collyria may be used in connection with diluted citrine ointment, or other suitable, topical applications, along the edges of the lids. When it appears during an attack of herpes zoster ophthalmicus, or ensues after paralysis of the orbicularis, caustics are scrupulously to be avoided as being likely to promote ulceration of the cornea, to which, in these circumstances, there is always a predisposition; only the mildest astringents should be used. In chronic thickening of the conjunctiva and eversion of the lids in old people, commonly called "blear eyes," attention should be given to the lachrymal passages, and the everted lid should be brought to its place by a frequent but mild use of astringents, patiently followed up. These should not be applied, nor should caustics be used, upon the everted and dry portion of the conjunctiva, as they only serve to harden, and, as it were, tan the surface; but the crayon of sulphate of copper or of alum should be applied, very lightly, to the non-everted portion of the conjunctiva. As this part becomes more healthy, the everted lid is drawn more and more to its proper place, the remedy can be applied more largely, and the improvement finally extends to the whole of the affected tissue.

The conclusions which seem to be warranted by the facts presented in the foregoing paper, may be summed up as follows:—

I. In a considerable number of essentially transient affections of the conjunctiva, and in pterygium or other growths, no active treatment by caustics or astringents is required.

II. When disease affects only a limited portion of the conjunctiva, as in phlyctenular inflammation, the mildest stimulating or astringent remedies are usually sufficient.

III. In the acute and chronic forms of general conjunctivitis, astringents are, as a rule, safer as well as more efficacious than caustics, and are, therefore, better adapted to the requirements of the general practitioner.

Discussion on Dr. H. W. Williams's Paper.

After the reading of the preceding paper, Dr. C. R. Agnew, of New York, said:—I would like Professor Williams to say with more minuteness what he would do in a case of ophthalmia neonatorum in which the swelling was so great as to produce complete eversion. Suppose he were called to see a child ten days old, in whom the inflammation was such as to have caused complete eversion of both eyelids; let him tell us what applications he would use, and how, and how frequently, he would use them. I agree mostly with Prof. Williams's views; I recognize the force of his arguments in favor of mild treatment, and the propriety of his protest against the too heroic measures often employed; but I want him to go further and tell us what he would do in such a case as I have described.

Dr. H. W. Williams said:—I can hardly imagine a case more unpleasant to meet with than such an one as that supposed by Dr. Agnew; nevertheless, those cases in which the excessively swollen, upper lid covers the lower, and confines the discharge, are even more dangerous. I would, however, prescribe treatment similar to that which I have advised in my paper, but should give very close personal attention to the case. I have never known the most critical stage in such cases to last longer than forty-eight hours, and I would make three or four visits every day, and be sure at each visit that the lids if everted were

placed in position, and the child not excited by the use of painful caustic applications. There is no difficulty in replacing the lid, but each time the child cries the lid becomes again displaced. The case should be faithfully followed up with mild local treatment. I would use the alum crayon, three or four times a day, as it causes little or no pain and does not distress the child, as would any strong or caustic solution.

Dr. E. WILLIAMS, of Cincinnati, said:—While I agree with the doctrines of the paper just read in many particulars, I disagree with them in regard to some essential points of treatment. It has been my custom to treat these cases much more energetically than is advocated in the paper, and I have never had a single case of ulceration occur during treatment in an infant. I evert the lids, thoroughly cleanse them, and brush them with a solution of nitrate of silver of the strength of from five to ten grains to the ounce, washing it off with salt water. Scarcely without exception the patient returns the next morning with eyes greatly improved. I continue this for three or four days, once a day, and when I have the disease under control continue the treatment by the use of astringents. I believe that in some cases the sulphate of atropia is very useful, but in infants half a grain to the ounce is as strong a solution as it is prudent to use.

Dr. H. W. WILLIAMS said:—I agree that in some cases it is well to use the stronger astringents, and perhaps an application or two of sulphate of copper. Sometimes I find it necessary to use active astringents, but even then, when danger is past, I return to the milder applications. I have known cases in which, lunar caustic having been used by the family physician, the eyes have been spoiled.

Dr. C. R. AGNEW said:—I would ask Prof. Williams how he would treat the worst typical case of gonorrhœal conjunctivitis, if called in within twenty-four hours, there being as yet no corneal lesion?

Dr. H. W. WILLIAMS said:—I have seen cases of that kind, with serous blood-stained discharges, in which I have thought it well to apply a strong astringent. I would say that I do not mean to limit myself or any other gentleman too strictly to the rules laid down. Every case must be treated by itself; but I have aimed to lay down a rule which is generally applicable.

Dr. JOHN GREEN, of St. Louis, said:—Prof. Williams's paper conveys the impression that in the purulent ophthalmia of new-born children success is uniformly to be expected if the case is treated early enough; nevertheless cases sometimes occur which do not turn out so well. I have seen two such cases in which the cornea was lost although carefully treated from the beginning of the attack.

Dr. GEORGE STRAWBRIDGE, of Philadelphia, said:—The modes of treatment which have been advocated are totally different, and yet have both been pursued by gentlemen of large experience. I have faithfully tried both methods. That which Prof. Williams, of Boston, proposes, is a good method when it can be carried out, but it is impossible to do that except in a hospital, or in a rich family, whereas these cases mostly occur among the poorer classes. My experience has been that after the acute stages have passed by, much benefit may be obtained from the use of the mitigated nitrate of silver.

Dr. S. D. RISLEY, of Philadelphia, said:—I have been struck with the extreme mildness of the treatment recommended by Prof. Williams. In the ophthalmia of new-born children, it has been my custom to use the mitigated stick, neutralizing any excess, as I can thus confine its action to the conjunctiva and spare the cornea. One other application which I have used with equally satisfactory results, is a twenty per cent. solution of carbolic acid in glycerine. It has the advantage of causing less pain than the nitrate of silver. Although painful at first, the pain subsides in a moment, and the child is subsequently more comfortable than after the use of the nitrate.

Dr. GEORGE C. HARLAN, of Philadelphia, said:—I see many of these cases at the Children's Hospital. Until four years ago, I never used nitrate of silver

of a strength greater than four grains to the fluidounce, but since then I have used as strong a solution as ten grains to the fluidounce, and so far from giving excessive pain it seems to give relief, and the children are more at ease after the immediate effects have passed off. In addition, I give directions for the use of an alum solution of the strength of five grains to the fluidounce as often as may be necessary to prevent the accumulation of pus.

Dr. J. H. Pooley, of Columbus, Ohio, said:—I employ the sulphate of copper, and it seems to me the better remedy for chronic conjunctivitis. I am not in the habit of using as strong solutions of nitrate of silver as Dr. Williams, of Cincinnati; using but five grains to the ounce. Stronger solutions I think very objectionable, and the mitigated stick cannot always be used without leaving a scar on the conjunctiva. I prefer to cleanse the eyes with a sponge rather than with a syringe, and I order the use of cold water.

Dr. E. Williams said:—I wish to say by way of explanation that, when I spoke of treating all infants uniformly, I did not mean to imply that I always employed solutions of the same strength. I have never seen more than two cases of diphtheritic conjunctivitis, and they were in children, not infants; each lost one eye. When we invert the lids, we see on the surface a somewhat grayish and consistent film, but this is easily removed and is not at all connected with diphtheria. I make it a point always to get this off. In speaking of my success I do not mean to disparage that of any one else, but I have found my plan of treatment successful, short, and certain.

Dr. William Thomson, of Philadelphia, said:—It seems to me that there is no difference of opinion with regard to the successful use of nitrate of silver, but only as to the mode of its application and the strength of the solutions to be employed. Applications made to the whole conjunctival sac, and so coming in contact also with the cornea, should not be stronger than two grains to the fluidounce; and I believe that it is generally better thus to bring the solution in contact with the whole conjunctival surface, than to make stronger applications to a part only of the diseased membrane.

Dr. C. R. Agnew said:—I feel somewhat embarrassed in telling what my views are, because I find that when we come to the subject of the report, we find cases behind the paper in which mild applications are confessedly not sufficient. We should stand ready to treat particular cases according to particular phases. If I find the eyelids sticky, and without much purulent discharge, my common direction is to bathe with a solution of common salt. If I find inflammation increased, and the discharge more watery, and wine-colored, I take the head of the child between my knees, bathe the eyes with water applied by a sponge, apply a solution of nitrate of silver, and then give some simple ointment to prevent the adhesion of the eyelids and the collection of pus. If the case goes on to a still worse condition, and it is evident that the cornea is to give way, I anticipate the evacuation of the aqueous humor by paracentesis. With regard to gonorrhœal ophthalmia, it is oftenest the case that it destroys the cornea within thirty-six hours, and that when it is not destroyed in this time, the case gets well. What we need to know is what to do when the lids begin to stiffen, and the fluid turns reddish or wine-colored. In a case of that kind I would give an injection of morphia in the corresponding temple, and run a pair of scissors into the external canthus, and cut down to the orbit, hoping to get a good spouting of blood. I would then pour water on the corresponding side of the head to encourage the bleeding, and finally repeat the application of morphia to produce sleep. Unless there is a decided improvement, I evert the eyelids and make an application of nitrate of silver, and afterwards apply iced cloths, which should be damp and cold, but not wet.

The President, Mr. R. Brudenell Carter, of London, said:—The differences in the treatment recommended are far more apparent than real, and would melt away in the presence of individual cases. Prof. Williams without doubt desires to show the danger of very strong astringents and caustics, and I believe that the Section will generally agree in his conclusions.

ON TUMORS OF THE OPTIC NERVE.

BY

H. KNAPP, M.D.,

OF NEW YORK.

A VERY limited number of tumors of the optic nerve has hitherto been recorded. W. Goldzieher, in a very valuable paper on the subject, published in Graefe's Archiv für Ophthalmologie, 1873, states that in modern medical literature he has found only six cases of the kind, to which he himself adds three others. I have found records of a few additional cases, and have seen three myself, two having been under my own care and one under that of Dr. E. Gruening at the New York Ophthalmic and Aural Institute. I shall give a brief sketch of some of these cases, in order to obtain the data necessary for a general description of the affection.

CASE I.—(Described by A. von Graefe, in his Archives, vol. x. part 1, p. 193 etc., 1864.) A farmer, æt. 23, had first noticed, two years previously, diplopia and protrusion of his right eye. The exophthalmos increased steadily, but the diplopia subsequently disappeared from the sight of that eye becoming lost. No pain was felt until a few weeks before the patient was first seen, when secondary infiltration of the cornea set in. On examination, there was found exophthalmos of 9‴, in the direction of the orbital axis; the lids could not be closed; the mobility of the globe was restricted inward, but in other directions was free; the centre of motion coincided with that of the globe. Behind the globe, a soft, elastic tumor was felt; S. = 0. The retinal veins were tortuous and dilated, the arteries attenuated. The inner half of the optic disk was swollen, with abrupt, slightly overlapping borders, reddish, and concealing the bloodvessels; the outer half was level.

Graefe diagnosticated a relatively benign, orbital tumor, probably of a fibro-sarcomatous nature. From the fact that the centre of rotation corresponded with the centre of the globe, he concluded that a stratum of loose connective tissue separated the tumor from the globe. The freedom of the outer half of the optic disk led him to the supposition that the blindness was not caused by compression, but by the immediate transition of the tumor to the nerve, or possibly by its origin in the nerve itself. The tumor being situated within the muscular funnel, and surrounding the optic nerve, its extirpation with preservation of the eyeball, he said, could not be thought of. He enucleated the eyeball, slit the stratum of connective tissue in front of the morbid growth, laid the bluish-red looking tumor bare, and removed it without difficulty. The operation was followed by alarming cerebral symptoms, intense headache and nausea; the pulse fell from 80 to 52 beats, and the temperature rose to 40° C. (104° F.). These symptoms subsided upon the appearance of an extensive suppuration in the wound. The patient recovered.

The tumor, examined by Recklinghausen, was pear-shaped, a little larger than a pigeon's egg, partially soft and gelatinous, and partially fibrous. The bulk of the optic nerve lay as a compact cord on one side of the tumor, and was covered, together with the whole tumor, by a tough, fibrous capsule. The limit of the nerve which looked toward the tumor, was ill-defined. The fibres of the cord-like portion of the optic nerve were preserved in their whole course, the others entered the tumor and were lost in it. This condition was found

in both the cut ends of the nerve, that is at its entranee into and its emergence from the tumor. The growth therefore was a *myxoma* of the optic nerve, originating in the inner sheath and perineurium internum. The swelling of the inner half of the intra-ocular end of the optic nerve was caused (according to the examination of Schweigger) "by a proliferation of indifferent (lymphoid) cells, as might be expeeted in so young a formation."

Case II.—(Deseribed by A. Rothmund, Zehender's Klin. Mon., 1863, S. 261.) The patient was a healthy looking girl of fifteen years. At the beginning of her second year, her left eye began to be pushed forward and downward, and was excessively painful. She could see with that eye. In the course of four or five months the eye became blind, but kept free from pain; yet the lids were swollen every now and then. From that time to her sixteenth year, she felt no annoyance from the eye, though it slowly but constantly grew larger. When seen by Dr. R., the orbit was occupied by a roundish, faintly fluctuating tumor, the size of a large hen's egg. The tumor was totally covered by congested conjunctiva, but incompletely by the lids, and moved harmoniously with the healthy eye in every direction. Remnants of the cornea were recognizable at its apex, which was very tender to the touch. The palpebral fissure was two and a half inches in length, and the orbit was greatly distended.

Dr. Rothmund removed the tumor in the manner of an ordinary enucleation. Its pedicle was severed near the optic foramen. In some weeks the orbital wound was closed by granulations. The patient recovered.

At the posterior end of the tumor a piece of the optic nerve, 3‴ in length, was preserved. The growth was a total degeneration of the optic nerve, consisting of fibrous tissue which inclosed smaller and larger cysts, the cavities of which were pervaded by a network of white, delicate fibres containing a vascular, gelatinous substance. The microscopic examination, made by Prof. Buhl, showed the characteristics of a *myxoma*, which is frequently met with in other nerves. The eyeball had been flattened by the tumor in such a way that the optic disk touched the cornea.

Case III.—(A. von Graefe, Arch. f. Ophth., x. 1, S. 201, 1864.) The patient was a young lady, æt. 24, who for two years had noticed a slight exophthalmos with amblyopia and contraction of the visual field of her left eye. With the ophthalmoscope Graefe discovered choked disk and spontaneous arterial pulsation. During the next five years the exophthalmos slowly increased, while sight was reduced to quantitative perception of light. The exophthalmos measured 8‴, and showed a marked deviation outward. Mobility preserved, but reduced in every direction. The centre of rotation corresponded approximately to the centre of the globe. A soft tumor was located immediately behind the eye, more on the nasal than on the temporal side. Between the upper and inner recti muscles it could be seen through the conjunctiva as a smooth, reddish-yellow intumescence. In the outer part of the field of vision, there was no perception of light. The optic disk was atrophic.

The patient was operated on by Langenbeck, who first enucleated the eyeball, and then the tumor, which did not extend to the apex of the orbit. It was as large as a pigeon's egg. The optie nerve passed as a flattened cord along its nasal side, but a considerable part of it entered the tumor and was lost in it. The posterior part of the eyeball was flattened by the pressure from the tumor.

The tumor, examined by Recklinghausen, was found to be a *myxo-sarcoma* of the optic nerve. Its anterior part contained a cyst, around and behind which there was a soft, partly gelatinous substance, eonsisting of very delicate, interlacing fibres which inclosed round and oval cells. The gelatinous liquid which could be pressed out of the tumor grew very opaque on addition of acetic acid. Larger portions of the tumor showed a substanee almost entirely composed of cells, between which some larger bloodvessels ramified.

Case IV.—(Described by E. Neumann, in Archiv für Heilkunde, xiii. S.

310.) The patient, æt. 20, had suffered from headache for six years, and had noticed a protrusion of her eye for three years. The mobility of the eye was preserved, and was only a little restricted in an upward direction. The vision was almost normal. On palpation a hard immovable tumor was felt surrounding the posterior part of the globe on all sides. Dr. Jacobson, of Königsberg, removed the eye together with the tumor.

The tumor was three-quarters of an inch in length, the size of a walnut, and immediately behind the eye surrounded the optic nerve, which passed quite loosely across it. The neoplasm was connected with the outer sheath, which on section showed itself as a distinct, white border-line. The inner sheath was smooth and shining. Between the two sheaths, delicate cords were stretched when the nerve was drawn away from the tumor. The microscopic examination discovered that the structure of the tumor was partly compact, partly alveolar. The alveolar part had a stroma which resembled that of a cancer, inclosing accumulations of fusiform cells in concentric layers. The centres of many cells were incrusted. Teased preparations showed that these fusiform elements were flat endothelioid cells. The compact part of the tumor consisted of coarse fibrils, here and there inclosing numerous accumulations of sarcomatous cells. The periphery of the tumor consisted of adipose tissue. The tumor is styled by Neumann a *psammoma*, on account of the prevalence of the incrusted, arenoid bodies in the alveolar part of the tumor.

Case V.—(Described by H. Knapp, in Archives of Ophthalmology and Otology, vol. iv. pp. 323–354, 1875, with four plates.) Mrs. J. K., æt. 40, was first examined in August, 1871. Her left eye was normal in function and structure; the right protruded about 5‴ in a forward and slightly downward direction. The protrusion had begun six months previously, and the sight of that eye had gradually become impaired. She suffered from occasional headaches, which always increased the protrusion of the eye. The movements of the globe were somewhat restricted, chiefly in an upward direction. There was no pulsation, nor bruit. S. with +10 Sn. $\frac{20}{100}$; F. complete. The optic disk showed a steep elevation, arteries small, veins dilated and tortuous. The ophthalmoscopic condition did not materially change for three years. In June, 1874, a hardish tumor was felt, on palpation, on the inner and upper side of the posterior part of the globe. It moved with the eye. A free space was felt between the tumor and the orbital wall. The globe was dislocated slightly outward, and considerably downward (4‴–5‴), but mostly forward (6‴). Inversion was perfect, whereas the strongest eversion brought the corneal margin no nearer than 2‴ from the outer commissure; downward rotation was free, but upward rotation moved the eye no higher than the horizontal median plane; S. $\frac{10}{200}$. F. complete. Media clear, pupil responsive. Papilla raised, with abrupt borders, like a "jockey-cap." Venous hyperæmia marked. General health good. For the last years, great pain in eye and head. The diagnosis of orbital tumor could now be more specifically revised into that of a tumor of the optic nerve, and acting upon this supposition I attempted, on June 10, 1874, to enucleate the tumor while preserving the eyeball. I succeeded in the following manner:—

I opened the conjunctiva by a circular section between the inner and superior recti muscles, and laid the anterior portion of the tumor bare. Then I introduced my left forefinger into the wound, and under its guidance freed the hardish tumor from the soft, surrounding orbital tissue. After that, I dissected the mass from the posterior part of the globe, with which it was connected by a thin layer of connective tissue. Further, I severed the optic nerve, and then introduced my finger as deeply into the orbit as possible. Not being able to reach the apex of the tumor, which was close to the optic foramen, I cut the tumor across as near the summit of the orbit as I could reach. Now I rotated the growth on its antero-posterior axis, and severed such connections with its surroundings as had before escaped. All this was done with a pair of strabismus scissors. Then I introduced the closed blades of a stronger pair of

scissors, curved on the flat, behind the tumor, and lifted it out of the wound. This produced sufficient free space in the orbit to enable me to remove the little part of the tumor which had been left. I seized it with a pair of strong scissors, had it drawn forward by an assistant, and excised it, always using my left forefinger as a guide. The eyeball, which had been turned aside, was replaced, and the conjunctival wound closed by sutures. Though the tumor was located within the recti muscles, none of them had been cut. The tension of the globe was not changed. The inner half of the eye was anæsthetic, the outer half sensitive, though a little dull. The fundus gave a reddish reflex, but its details could not be seen on account of irregular detachment of the epithelium from the cornea, giving the latter the appearance of frosted glass.

The reaction from the operation was very moderate. The patient now totally lost her headache. On the third day the fundus oculi was visible, and appeared uniformly milky-white. A small whitish-gray infiltration was noticed on the lower part of the cornea. On the fourth day this infiltration had increased, but the fundus could be seen through the clear part of the cornea above it. In the milky surface two dark-red streaks were visible, which had increased the next day, and proved to be the main branches of the retinal veins. Every day new retinal vessels were filled with blood, and in some weeks there was a picture of very marked retinal congestion. (See Fig. 2, Tab. IX., Arch. Ophth. and Otol., 1875.) The fundus had so far cleared up that only the region around the papilla and yellow spot appeared milky, the remainder having its natural color. Gradually this milky appearance disappeared, and then extensive retinal hemorrhage took place, which disappeared slowly, and left the retina and inner part of the choroid atrophic and degenerated. (See Plate X., loc. cit.) The infiltration on the lower part of the cornea, which I have mentioned above, disappeared after the eye had been protected by carefully closing the palpebral fissure. The cornea has never since lost its lustre, and but little change took place in the interior of the eye for two years. Lately, some membranous opacities in the vitreous have appeared. The eye has its natural size, is a little more deeply set in the orbit than its fellow, squints somewhat inward and downward, but has not been the cause of any annoyance. The cornea is bright throughout, though its inner half is still as anæsthetic as immediately after the operation. At this time, two years and three months after the operation, the tension of the eye is diminished, and there is some blood in the vitreous. The patient looks healthy, and there are no symptoms of a relapse.

The tumor was a little above the size of a walnut (30 by 27 mm.), and uniformly hardish. Its base was slightly concave, covered with a thin layer of connective tissue which had united it to the sclerotic. The optic nerve passed through it. The outer sheath of the nerve was well recognizable, though its fibres were more or less separated by the elements of the pseudoplasm. The intervaginal space was a little enlarged, and filled with the tissue of the growth. This, when well hardened in Müller's fluid, was uniformly finely granular. It had no capsule proper, but was loosely covered with the adipose tissue of the orbit. Under the microscope, the growth showed a typical specimen of *scirrhous cancer.* A stroma of fasciculated connective tissue inclosed alveoli filled with epithelial cells, which had no more intercellular substance between them than was necessary to cement them. In the neighborhood of the nerve, a limited number of arenoid bodies (sand-globules) were seen embedded in connective tissue, yet not numerous enough to give even a part of the tumor the character of a psammoma. The whole growth was very vascular, and a good part of its stroma had undergone colloid degeneration. The inner sheath was thickened, and infiltrated with colloid and lymphoid bodies, nowhere with cells of an epithelial character. The interfascicular tissue of the nerve was somewhat thickened. In it, and between the nerve fibrils, there were very numerous lymphoid cells, either single or arranged in rows and clusters; *inflammation of the nerve.* The same change was seen in the intra-ocular end

of the optic nerve—a well characterized specimen of *neuritis optica descendens*. For a detailed description of the specimen, and remarks on many interesting points connected with this case, see Arch. of Ophth. and Otol., vol. iv., 1875, pp. 323 et seq., and Plates IX.–XII.

Case VI.—(Described by L. Krohn in Zeh. Klin. Mon., 1872, S. 103–108.) A married woman, thirty years of age, had a tumor the size of a fist in the right side of her abdomen. It had begun six months previously with local pain, which was followed by general debility, emaciation, headache, vomiting, and gradual loss of sight in both eyes. A tumor was also developed in the left side of the abdomen. The eyes, when examined six months after the beginning of the disease, were totally blind, and, ophthalmoscopically, exhibited marked pictures of choked disk, with some retinal hemorrhages. The patient died eight months after the beginning of the disease.

The autopsy showed *carcinomatous tumors* of both ovaries; all the other organs were normal; the cranial cavity in particular contained no morbid formation. There was a small intumescence in each optic nerve near the sclerotic. The intumescence was caused by a new formation in the intervaginal space, consisting of a tissue which was rich in large round and polygonal cells, and had the arrangement of a cancer. The same kind of cells pervaded the inner sheath and the interfascicular connective tissue, and were very numerous around the central bloodvessels. They extended in the nerve and intervaginal space as far as the lamina cribrosa, but did not enter the eye. On the other end, they could be followed a little beyond the optic foramen. The intra-ocular end of the optic nerve was infiltrated with lymphoid bodies.

Case VII.—(Described by V. Szokalski, in Annales d'Oculistique, t. xlv. p. 43, 1861.) A boy of four years, healthy and well nourished, had a considerable forward protrusion of his left eye, which was perfectly movable. His parents attributed this condition to a severe contusion of the temple, received four or five months previously. The sight was good; by ophthalmoscopic examination, the retinal veins were found enlarged. The exophthalmos increased, the eye became very painful and sensitive to light, the lids could not be closed, the cornea grew opaque, the eye blind, and the other eye became the seat of sympathetic irritation. There was no tumor felt between the globe and the orbital walls; but the orbital tissues were a little more prominent and elastic than usual. None of the symptoms of a vascular tumor were present. Szokalski made the diagnosis of *cystic tumor* directly behind the eye, near the optic nerve, within the recti muscles. He extirpated the contents of the orbit. After having enlarged the palpebral fissure and made a circular incision around the globe, close to the orbital wall, he felt with the finger a hard, nodular, and movable tumor behind the globe, which he isolated from its surroundings by incisions along the orbital walls (*rasant les parois de l'orbite*); then he drew it forward with a strong hook, and, with scissors, severed it near the summit of the orbit. A profuse hemorrhage was arrested by placing a piece of ice in the orbit for two minutes.

The eyeball proved to be quite healthy. A centimetre behind the globe, the optic nerve entered into a nodular, transversely oblong tumor, the size of a filbert, through which the nerve passed in the direction of its smaller diameter, like a string through a bead. Its outer sheath passed directly over the tumor, where it became thicker and more adherent. The substance of the tumor was hard, grayish, fibrous, grating under the knife; it presented under the microscope, reticular areolæ, in the midst of which, caudate, uni-nucleated or multinucleated cells were accumulated. The nervous fascicles, after their entrance into the tumor, spread like a fan and were imperceptibly lost in its centre; on its other side they reappeared, and entered convergingly into the other end of the nerve. The growth "undoubtedly took its origin in the neurilemmatic partition-walls of the optic nerve, and unquestionably was of the nature of a scirrhous cancer." Though the nerve was divided as near the optic foramen

as possible, its transverse, cut surface showed, by its gray color, that the pseudoplasm had already penetrated into the cranial end of the nerve.

The wound healed so rapidly that the patient was able to leave the hospital at the expiration of three weeks. For almost five years the boy was in good health, but then a local relapse took place. When he presented himself again, the orbit was filled with a hard, somewhat elastic tumor, which projected in the shape of a small apple beyond the distended eyelids. The child was pale, but otherwise healthy, and complained of some lancinating, periorbital pain. The tumor was nowhere adherent to the orbital wall, and, therefore, easily removed. The patient did well enough during the next two days, but, on the third, convulsions and vomiting set in, and he died of meningitis on the sixth day after the operation.

An autopsy revealed congestion of the pia mater at the base of the anterior lobes, and a greenish, sero-purulent exudation at the anterior part of the base of the skull cavity. Under the left anterior lobe, in front of the Sylvian fossa, was a tumor, as large as a nut, growing from the degenerated optic nerve without implicating the chiasm. The adjacent brain substance was softened. The tumor was dense and consisted of a scirrhous substance.

The optic foramen was dilated and filled with a granulated, reddish substance, which connected the cranial with the orbital tumor. The orbit was enlarged to about twice its natural size, mainly at the expense of the ethmoid and maxillary sinuses. The tumor removed from the orbit contained on its posterior side a large cyst, which had been opened during the operation and had yielded about two ounces of a yellow serum. Sections in different directions through the tumor displayed a scirrho-cancerous, lardaceous substance, grating under the scalpel. Some softened portions of it contained a brain-like substance.

I have made a detailed extract of this case on account of its singular clinical and pathological interest. The original and secondary tumors are pronounced scirrhous cancer by the author, yet his description does not fully convince me. The original tumor may have been a fibroma, and the relapsing tumor a myxo-fibroma. According to the author, both tumors were scirrhous cancers, the secondary one having undergone partial softening in its interior.

These seven cases, together with eight others, form the material from which I shall endeavor to frame a general description of the affection under consideration.

Pathologically, the following species of tumor have been observed :—

(1) *Myxoma*, in five cases.
(2) *Fibroma myxomatodes*, in two cases.
(3) *Sarcoma myxomatodes*, in two cases.
(4) *Glioma myxomatodes*, in one case.
(5) *Fibro-sarcoma*, in one case.
(6) *Psammoma* (perhaps alveolar sarcoma or carcinoma), in one case (E. Neumann).
(7) *Scirrhous cancer*, in two cases.
(8) *Secondary cancer*, from primary cancer of ovaries, in one case.

The majority of these tumors consisted either of pure mucoid tissue (five cases, 33 per cent.), or contained a considerable proportion of mucoid substance in addition to their prevalent tissue. In most of these cases the pseudoplasm originated in the inner sheath and the interfascicular connective tissue of the nerve. To these should probably be added the case of scirrhous cancer of Szokalski, the recurrent tumor in which case contained also a large cyst. In three cases (glioma myxomatodes, fibro-

sarcoma, and secondary cancer) the tumors may have sprung from the tissue of the subvaginal space and the inner sheath. Two tumors of a carcinomatous structure (Neumann and Knapp) originated in the outer sheath.

Symptomatology.—The age of the patients varied from one and a quarter to forty years. There is no decided preference for either eye. The prevalent symptom is exophthalmos, either directly forward, in the direction of the orbital axis, or showing besides a secondary deviation in accordance with a greater development of the tumor on one side. The motions of the globe are preserved, but more or less restricted. On palpation, directly behind the globe a softish tumor is felt, the movements of which correspond more or less to those of the eyeball. A free space can be recognized between the tumor and the orbital wall. Neuritis descendens is a constant symptom in the early stages, and atrophy of the nerve in the later stages of the affection. The sight is more or less impaired, the field of vision being restricted when the pseudoplasm originates in the inner sheath and perineurium internum. Sight is less impaired, and the visual field remains complete, when the tumor springs from the outer sheath. Intense and persistent pain has been noticed in the cases of cancer (Neumann, Knapp, Krohn); in the other cases there was pain only when the eyeball was inflamed, with the exception of one case of myxoma (Gruening) in which intense pain was felt after the protrusion of the eye had existed for four years without pain.

The *course of the disease* shows in all cases a slow but steady increase of the tumor. The longest duration observed was fifteen years (Heymann and Rothmund). First, the posterior part of the eyeball is flattened, and the eye becomes hyperopic; then the eye protrudes, and neuro-retinitis sets in; then opacity, ulceration, and perforation of the cornea occur; after which the coats of the eye are so much pressed together that the optic disk touches the cornea. The ultimate, spontaneous issue cannot be known from the published cases, since the tumor in all was extirpated, and recovery took place, except in one case in which a relapse implicating the brain occurred, and in which the patient died from meningitis in consequence of a second operation.

The observations on record are not sufficient to enable us to form a reliable *prognosis* as to the natural course of tumors of the optic nerve. All the cases in which the tumor was removed ended in recovery, which, with the one exception of a fatal recurrence, seems to have been permanent. Sight is, of course, destroyed in all cases.

The *treatment*, until lately, consisted in the removal of the tumor, together with the eyeball, which operation offers no difficulty. Two years ago, I succeeded in removing such a tumor, and preserved the eye. About one year since, Dr. E. Gruening did the same in another case. Both of these cases have continued to do well. In one case (Graefe), the operation was followed by suppurative inflammation in the wound; in another (Szokalski), the operation caused death by meningitis. In none of the other cases was the operation followed by any unpleasant symptom.

In conclusion, I may say that tumors of the optic nerve form, at present, a sufficiently understood chapter of surgery, and that their differential diagnosis is quite possible. Extirpation relieves the patient from disfigurement and pain, and prolongs life. By improved modes of operative procedure, the tumor may be removed while the eye, which, though blind, is better than a glass eye, is preserved.

ORBITAL ANEURISMAL DISEASE AND PULSATING EXOPHTHALMIA; THEIR DIAGNOSIS AND TREATMENT.

BY

E. WILLIAMS, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN MIAMI MEDICAL COLLEGE, CINCINNATI.

The differential diagnosis between genuine intra-orbital aneurism and pulsating exophthalmia from other causes, is by no means easy. Till recently, all cases of protrusion of the eyeball, with pulsation, were set down as orbital aneurisms as soon as encephaloid, meningocele, and one or two other rare affections, had been excluded. A careful study of the literature of the subject, in the light of pathological anatomy, has unsettled this long established opinion. The case of so-called aneurism by anastomosis, in the orbit, published by Travers in 1808, presented symptoms, in common with many that have since been published, that are now known to be frequently present in affections of the vascular system entirely outside of the orbit. A warm difference of opinion prevailed as to whether these were cases of aneurism by anastomosis, or of circumscribed or diffused aneurism of the ophthalmic artery. But all located their starting point in the orbit.

Such were the views generally entertained till the publication of Nélaton's celebrated case in 1856. True, Baron, in 1835, had presented to the Paris Anatomical Society a specimen of aneurism of the carotid in the cavernous sinus, in which the symptoms, during life, had been pulsating exophthalmos and intense murmur heard by the ear over the protruded eye. These were the typical symptoms that passed current for orbital aneurism, both before and after that time. The strong significance of this observation was not then noticed. In 1853, Aubry had the good fortune to secure an autopsy in a patient in whose case all the symptoms of orbital aneurism had been present, and that diagnosis had been made. No arterial lesion whatever was discovered. The ophthalmic vein was greatly dilated and its branches enlarged, forming the "bossy, vascular, pulsating tumors observed during life." The vein was as large as the little finger, and its coats very thin, and it freely communicated with the greatly dilated cavernous sinus. The sinus terminated behind in a *cul-de-sac*, the communication with the inferior petrosal sinus being cut off. Though observed in 1853, this case does not seem to have been published till 1864. In 1841, M. Gendrin made public a case with symptoms of orbital aneurism, in which a post-mortem examination showed this interpretation to have been incorrect. "The ophthalmic vein was varicose and distended with coagulated blood. The internal carotid and origin of the ophthalmic arteries were surrounded by an adherent clot, continuous with a clot infiltrated into the arterial tunics." Mr. Walter Rivington very plausibly explains this condition as indicating an aneurism of the internal carotid in the cavernous sinus, which had ruptured.

Nélaton's first case is so important in the pathological history of this disease, that I will transcribe it entire from Mr. Rivington's *resumé* of

cases in connection with his excellent paper on Pulsating Tumors of the Orbit, in the Medico-Chirurgical Transactions for 1875. In that paper he gives the most complete collection of cases, and the most systematic and thorough criticism of them, that I have met with. The case of Nélaton is as follows:—

"Male, 21. Right eye. Thrust with the ferule of an umbrella in the left lower eyelid. *Symptoms and Progress.*—Abundant bleeding from the nose, and ptosis of the right upper eyelid. Wound of the left eyelid healed rapidly, but at the end of some days the right eye became more prominent, with diplopia and mydriasis. Two months later, left eye was healthy; right eye prominent; ptosis; dilated veins on the surface of the upper lid; pupil largely dilated; external strabismus; absence of movements of the eyeball; diplopia. . . . . Patient blew blood habitually from the right nostril; paralysis of the right third pair; pulsation of the eyeball; *bruit de souffle* continuous, with re-enforcements during arterial pulse; absence of thrill. A little later, *bruit de miaulement*, audible also to the patient. He continued to blow blood from the right nostril, and at times had epistaxis." Nélaton diagnosed wound of the right carotid in the cavernous sinus. The patient died not long after from bleeding at the nose, and the autopsy fully confirmed the diagnosis. "The body of the sphenoid bone was fractured, and the right internal carotid was found torn across in the cavernous sinus. The sphenoidal sinus communicated with the cavernous sinus on the one hand, and with the nasal fossæ on the other, and through this communication the hemorrhage had taken place."

Hirschfeld, in 1858, had a case presenting similar symptoms, as the result of injury, in which the diagnosis of effusion of blood compressing the motor nerves before their entry into the orbit was made. Death occurred, and a blood clot was found in the cavernous sinus, enveloping the third and compressing the ophthalmic nerve. The clot covered a small circular hole in the carotid, which looked as if it had been punched out, and which was occupied by a string of decolorized clot about two inches long, and passing into the mass of coagulum. The bones were sound. This case is of great value, as it proves that the usually accepted symptoms of intra-orbital aneurism may be produced by a lesion of the carotid artery; and also that a sharp blow on the face or head, without fracture of the base of the skull, may cause a rupture of the internal carotid. Nunneley had occasion to make a post-mortem examination of a patient whose carotid he had ligated five years before for orbital aneurism. He found a circumscribed aneurism of the ophthalmic artery at its origin *in the cranium.* In another similar case the post-mortem appearances seemed to indicate the existence of an aneurism of the internal carotid, which had ruptured into the cavernous sinus. These cases and others induced Nunneley to look for the seat of so-called orbital aneurism rather in the cranium than in the orbit. In a paper, in 1864, he says: "In the great majority of such cases of protrusion of the eyeball, there is no disease whatever in the orbit. The seat of it is most commonly intra-cranial. The protrusion of the eyeball is passive, and the other distressing symptoms are secondary, depending upon obstruction to the return of blood through the ophthalmic vein. That this pressure in the great majority of acute, spontaneous cases is caused by an aneurism of the carotid as it emerges into the cranium, or of the ophthalmic artery in its intra-cranial portion, near its origin, is I think now certainly proved." The cases of traumatic origin he explains in a different way, but by injuries and changes in the cavity of the cranium and not in the orbit.

In Bowman's case, in which "all the capital signs of orbital aneurism

58

were present in a high degree," there was no aneurism found after death. The cavernous sinus, and the circular, transverse, and petrosal sinuses, were filled with clot softening in the centre, and the enlarged ophthalmic vein was plugged at its opening into the cavernous sinus. The great Nélaton had a second case, with the current orbital-aneurismal symptoms, following a fall from a carriage, where death occurred after ligation. He had diagnosed an arterio-venous communication in the cavernous sinus. A fracture through the body of the sphenoid bone and pars petrosa of the temporal, was found on both sides. On the left side a sharp point of the temporal bone was detached, and had probably penetrated the carotid and the wall of the sinus. At all events there was found a small hole in the carotid, below and externally, connecting it with the sinus, which was dilated; and the ophthalmic vein was dilated and tortuous. In a case of Dr. Oettingen, the symptoms were much the same, excepting that the veins of the eyelids were not particularly affected, and that the bruit was audible only over the eye; the patient died two years afterwards. No arterial lesions were found, but there was partial obliteration of the orbital veins. Dr. Oettingen attributed the symptoms during life to thrombosis of the orbital veins, and alleges the case as proof that blocking of the orbital veins alone, with no trouble behind, may produce pulsating exophthalmos and bruit. In 1868, Wecker lost a patient fifty-two days after ligating the carotid. The symptoms were as usual. The post-mortem examination showed great dilatation of the ophthalmic vein, and extensive atheromatous degeneration of the inner coat of the carotid. As no description is given of the state of the cavernous and other sinuses, Rivington thinks it not improbable that the extreme dilatation of the ophthalmic vein and its frontal branches, forming "the pulsatile thrilling" tumors observed during life, may have resulted from the existence of a fissure in the internal carotid, in the cavernous sinus, which was overlooked at the post-mortem examination.

To aid in the differential diagnosis between orbital aneurism and other lesions which produce many of the same phenomena, I will give the particulars of three cases, in two of which I think that this rare affection really existed.

Case of Spontaneous Cure of Orbital Aneurism by Rupture.—Mrs. K., æt. 55, in good health, of medium size, rather spare in form, dark hair and eyes, sallow complexion. In June, 1875, her friends noticed an unusual redness of the right eye. She had had no injury, pain, sudden noise, or anything whatever to attract her attention to the eye, but remembers feeling some transient, neuralgic pains in the temple of that side. The injection of the eye increased slowly till September, when undue prominence was noticed. The congestion of the eye was increased by hard work, but was not influenced by straining or stooping. The exophthalmos had probably existed and increased for some time before it was observed.

The patient consulted me first in September. There was then a striking exophthalmos of perhaps a fourth of an inch, the ball presenting directly forwards and the movements being perfect, except for a slight limitation in all directions. No ptosis, no sluggishness of pupil, no diplopia, and V. = 1. By the most careful examination with the finger pressed between the globe and the orbital margin, no pulsating tumor was felt. But to the touch and to the eye there was a marked pulsation of the globe and the surrounding tissues. The subconjunctival veins were enormously injected and tortuous, forming a wreath around the cornea by their large and numerous inosculations. The ophthalmoscope showed the veins of the retina equally dilated and tortuous, with the usual appearances of choked disk, but I could see no pulsations. The arteries

were not as straight as usual, but otherwise not altered. For want of time to examine the case further, the patient was told to abstain from all hard work, stooping, or straining, and to return for further examination in a few days. When she returned I found her condition essentially the same. For want of time, I again deferred further examination till another day, which was fixed upon. I explained to her the serious nature of the disease, and what might eventually become necessary. To my great regret, I saw her no more for five months, so that I did not have a chance to watch the progress of the case.

On the 12th of February the patient returned with the following history. Up to three weeks before, her condition had continued the same as when I last saw her. There had been no increased pulsation; no enlargement of the vessels of the forehead or pulsating prominences around the eye; she had never heard any bruit with the pulsations, and was not conscious of the latter except as she felt the eye with the finger. She stated also that on January 20 the eye had become somewhat painful and more prominent, had throbbed more strongly, and by the next day had become extremely painful. Then the globe was suddenly pushed almost out of her head with excruciating pain and great redness. In her own language she thought that the eye would "burst out of" her head. She applied to her family physician, Dr. Fishburn, who reported to me in writing as follows:—

Mrs. K. first called my attention to her eye, in the evening of January 20, 1876. I made a hasty examination at the moment, regarded it as a mild case of conjunctivitis, and requested her to call next day. On the 21st I was summoned to see her at her home. I found her face so much disfigured by a swelling over the right eye, that I hardly recognized her as the patient I had seen the day previous. The eye had the appearance of having received a terrible contusion from direct violence. The swollen and discolored lids were so firmly closed that it was impossible to separate them, and the effort caused exquisite pain. I directed the constant use of cold water and acetate of lead dressings, and a saline purgative, to be followed by quarter of a grain doses of morphia every three hours till the pain should be relieved.

22d. Patient worse; could not bear the cold water dressings; removed them and applied dry heat, which gave some relief. I ordered four leeches, to be followed by fomentations of poppy capsules.

23d. Found her very much improved; pain had moderated and swelling subsided considerably. I was now able to separate the lids; found the conjunctiva in a highly inflamed condition, and the tumefaction so great as to cause the ocular and palpebral portion to protrude between the lids, while a chemotic swelling surrounded the cornea. There was also great protrusion of the eyeball. Ordered a three-grain solution of atropia to be applied every three hours, and continued the anodyne fomentations, covering them with oiled silk.

24th. Patient improving; treatment continued.

25th. Improvement, and same treatment. In addition, I applied to the conjunctiva, with a brush, a few drops of a solution of nitrate of silver, gr. vj–f℥j.

26th. Swelling of the lids, and vascular congestion subsiding. The same treatment was continued till Feb. 12, when the patient was again referred to Dr. Williams.

At this time the exophthalmos was much greater than when I had seen the patient in September. The cornea stood half an inch in advance of its natural position, and was hazy, with extensive abrasion of the epithelium, and an intense zone of circumcorneal redness. I attributed the keratitis to the great prominence and exposure of the cornea. The patient said that her eye was much less prominent now than three weeks before, after the severe attack of pain and protrusion. Vision was very imperfect, explained in part at least by the state of the cornea. Movements of the eye much limited, but equally so in all directions, and no diplopia; pupil dilated by atropia, which had been constantly used. *There was now absolutely no pulsation felt anywhere* over the globe, or between it and the orbit. The eye could be pressed into the socket a line or more, but did not pulsate in the least, neither was any bruit to be heard on auscultation. Fundus of the eye dimly seen by the ophthalmoscope, and great swelling of the disk recognized. Ordered free use of atropia, and eye to be kept closed by wet bandage and compress.

Feb. 14. Improving rapidly; exophthalmos much less; cornea clearing; V. = $\frac{15}{80}$, with + S. 40. Choked disk, and remarkable enlargement and serpentine appearance of the veins, extending to the extreme periphery of the retina, with isolated points of ecchymosis. The arteries are small, partially obscured, especially on the papilla, but pulsate distinctly when pressure is made on the globe.

Feb. 21. Ball receded decidedly; cornea clear; V. = $\frac{15}{30}$, and patient reads No. 8 at 8″ with + $7\frac{1}{2}$; field of vision perfect; external vessels smaller, and eye less red; movements perfect.

Feb. 26. Eye receding; sclerotic less vascular, and showing white; V. = $\frac{15}{30}$; spots of effused blood still seen, especially at the sudden flexures of the retinal veins; outlines of the disk not yet sharp. Through March all the symptoms continued to improve.

April 8. The external vessels have disappeared above and below; the sclerotic looks more natural, and the exophthalmos is reduced to barely one-sixth of an inch; vessels of retina much smaller and straighter, and the hemorrhages becoming absorbed. Patient feels no inconvenience from the eye, and is gaining sight with the general improvement. On the 10th of June the patient is still better. Only two vessels forming a loop near the outer margin of the cornea attract attention. With this exception the eye appears as well as the other. There is a very slight degree of exophthalmos, not noticeable to the patient or to her friends; movements perfect, and pupil of medium size, but sluggish like the other; V. = $\frac{20}{30}$ with + 36. Fundus greatly improved; no traces of blood; disk nearly natural; and veins reduced in size and but little winding. On September 29, the patient called, at my request, for examination. The eye was perhaps one-twelfth of an inch more prominent than the other, but this could not be noticed without a critical examination. No trace of the external, enlarged vessels was seen except two small ones with a slight loop on the outer side of the cornea. V. = $\frac{20}{20}$ with + 42, almost equal to the other eye. On ophthalmoscopic examination, with dilated pupils, I could detect no material difference in the fundus of the two eyes, both appearing normal, and the arteries pulsating under same external pressure. By pressing the eye backwards with the finger, it seemed to be checked by a firm substance at the apex of the orbit, which did not exist on the other side. The patient was perfectly well.

I wish now to consider the question of diagnosis. Am I justified, in the present state of our knowledge on this subject, in calling this a case of intra-orbital aneurism? The symptoms of aneurism were, it seems to me, unmistakable. The pulsations of the protruded ball were synchronous with the systole of the heart, partly controlled by pressing the globe backwards against a yielding, elastic resistance, and completely stopped by pressure on the common carotid. I unfortunately lost the opportunity to investigate the *bruit de souffle* with the aid of the stethescope, but there is every reason to believe that it was there, and that it could have been heard. An important point in favor of the theory of orbital aneurism is that the patient herself never heard any bruit. In the great majority of intra-cranial aneurisms, the sound to the patient is audible, and often very distressing. In orbital aneurism, further away from the auditory nerve and labyrinth, with little or no direct bony conduction, I apprehend that the pulsations are not heard by the patient himself. There was no paralysis of any of the nerve trunks which pass near the cavernous sinus, and which are so often affected by direct pressure in cases of arterio-venous aneurism of the internal carotid. In short, all the symptoms were limited to the orbit, and all of an aneurismal character. The aneurismal sac was not very large, else it would have been felt by deep pressure of the finger; and it was not sufficiently firm to produce paralysis of the muscles and optic nerve by direct compression.

There was no dilatation of the branches of the ophthalmic vein, forming pulsating tumors, as in arterio-venous aneurism in the cavernous sinus.

The only serious obstruction to the return of the venous blood from the orbit, was confined to the veins of the eyeball, external and internal. The trunk of the ophthalmic vein could not have been seriously compressed without manifestations in its frontal and other branches. The symptoms were therefore all arterial in their origin, and confined to the orbit and globe of the eye. No well-authenticated case of arterio-venous aneurism in the orbit has ever been demonstrated by post-mortem examination. Besides, the symptoms were not of a character to make that supposition possible, much less probable. Of course encephaloid, meningocele, and venous tumors are excluded. It was not an erectile tumor, nor an aneurism by anastomosis in its restricted sense. The history, symptoms, and termination, all point to a circumscribed aneurism of the ophthalmic artery, in the orbit, which eventually ruptured, became diffuse, and was cured. I do not think that anything but an arterial hemorrhage could have pressed the globe so far forward and produced such extreme tension. That the aneurism must have been sacculated, with thin elastic walls and a small communication with the ophthalmic artery, is rendered probable by the occurrence of rupture and recovery without obliteration of the artery. That the artery is not obliterated, is sustained by the fact that arterial pulsations are observed in the optic papilla when external pressure is made on the ball. It could only be such a cause that would fail to produce more serious pressure on the ophthalmic vein, the rotatory muscles, and the optic nerve. That circumscribed aneurism of the ophthalmic artery does occur, though perhaps very rarely, is proved by the post-mortem examination in Guthrie's case, in 1825, where an aneurismal pouch was found on the artery in each orbit.

Some years ago also I treated a case in which I feel confident that there was an intra-orbital aneurism. The case was that of a young man who was shot in the eye by a small pistol. The ball passed through the globe and lodged deep in the socket, causing the eye to collapse and atrophy. The patient was treated by the late Dr. Blackman, and some months afterwards came to have an artificial eye inserted. On examination I found a round, pulsating, elastic, compressible tumor in the back and inner part of the orbit, about the size of a pigeon's egg. The man was not aware that anything was the matter till I called his attention to it. There was an aneurismal bruit heard with the stethoscope placed over the tumor, but not heard over the head or by the patient. It was exactly synchronous with the action of the heart and was completely stopped by pressure on the carotid. There were no venous enlargements in the socket or on the forehead. The globe was reduced to the size of the end of my little finger, so that the tumor could readily be seen and fully examined by palpation. I put the patient in the recumbent position, with the head raised; gave careful doses of digitalis, and had digital compression of the carotid tried for two days. It became irksome and painful to the patient, and my assistants gave out. So I called in Dr. Blackman, and we agreed to try instrumental compression of the carotid, which succeeded in completely curing the disease; and I afterwards fitted the patient with an artificial eye. He lived till recently, and died of phthisis.

These two cases are, I think, shown with reasonable certainty, by the symptoms and result of treatment, to have been genuine examples of orbital aneurism. In my case, published in the Medical Record, 1868, diagnosed as orbital aneurism and cured by ligation of both carotids, thirty days apart, I am now satisfied that there was an arterio-venous aneurism of the carotid in the cavernous sinus. I have since seen a case

with essentially the same symptoms produced by the passage of a cart wheel over the man's head. I never saw the man but once, and know not what became of him.

Case of Suspected Orbital Aneurism.—R. W., æt. 24, of stout figure, robust health, and sanguine temperament, was injured by the horn of a calf on January 18, 1876. The point of the horn struck the lower lid, glancing inwards and backwards and entering the orbit just above the tendo-oculi, causing an ugly contused wound and a severe concussion. The wound bled profusely, but healed in the course of a week, without surgical treatment. There was no bleeding from the nose, nor ocular hemorrhage, nor was the patient rendered unconscious by the shock. Sight was not affected, and there was no diplopia, headache, giddiness, nor other symptom of injury of the brain. There was no protrusion noticed. About five weeks after the accident, while stooping and driving a cross-cut saw, a sharp pain was felt above the right eye, running back over the ear to the temple. This sharp, peculiar pain came on at intervals, several times during the day, but was always provoked by stooping and straining, and soon passed off when the patient straightened himself up, and rested from sawing.

There was no giddiness, throbbing, or bruit. Late in April it was first noticed that the sight of the eye was misty at times, but without pain or other symptom of trouble. For this failure in sight a physician was consulted, who first detected an undue prominence of the eye. From that period, about May 1, till within the past four weeks, the exophthalmos increased slowly, but varied very perceptibly between morning and evening, being always greater in the morning. Since then it has remained stationary. When I first saw this patient, three weeks ago, there was a striking exophthalmos of over one-fourth of an inch, with slight injection of the sclerotic conjunctiva, and some serous, chemotic swelling within the external commissure. Corresponding to this were seen some large, deep-seated, inosculating vessels on the sclerotic. The pupil was larger than the other, and somewhat sluggish. The movements of the globe were limited by the prominence and the stretching of the muscles, but there was no paralysis. There was a divergence of $1\frac{1}{2}'''$ when fixing with the other eye, and the motion upwards and inwards was less excursive, but there was no diplopia, which I explained by the imperfect sight. Strongly marked features of swollen disk, and some neuritis; boundaries of disk obscured, and veins very large and tortuous to their extreme branches; slight alteration of macula lutea, blurring its distinctive features. Vision very defective in consequence of a large central scotoma, which patient expresses as well defined but not complete.

Tension of the globe natural. *No pulsation whatever of the globe nor bruit on auscultation.* When the eyeball is pressed directly backwards, it is arrested by a solid resistance. Diagnosis: Tumor of some kind at apex of orbit, probably of an aneurismal nature. In the complete absence of the three most characteristic symptoms of aneurism, pulsation, bruit, and some degree of elasticity on pressure, I rely upon the evident traumatic origin of the difficulty; its peculiar history; the absence of inflammatory symptoms, and the exclusion of the symptoms of either benignant or malignant tumor at the apex of the orbit. The symptoms followed so soon after the injury, and in the beginning were so characteristic, as to make this opinion more probable than any other. The sudden, sharp, severe pain running backwards over the temple, and caused by stooping and straining, coming on about four weeks after the blow, might be explained by the sudden rupture of the ophthalmic artery, directly as it enters the orbit through the optic foramen. Its coats may have been weakened by the original concussion, or the very slight rupture occurring there might have been plugged by the formation of a coagulum. The history of several published cases of supposed orbital aneurism, makes this latter supposition at least tenable. If the vessel then split or the plug was then suddenly dislodged

by the increased congestion from stooping and straining, why did not immediate protrusion of the eye, pulsation, bruit, etc., occur? It may be that the opening was very small, and close in the narrow apex where rapid expansion and consequent protrusion were prevented. It will be remembered that not till this occurrence was the vision impaired; and that the troubled sight took the patient to a physician who first detected the exophthalmos. The immediate effect of a slow oozing of blood from a small arterial rent in the supposed situation, would, of itself, be pressure upon the optic nerve and very slow protrusion of the ball without pulsation. As the sac, fed by so small a source, enlarging almost imperceptibly, may be filled as it forms with coagulated blood, and make a solid mass without pulsation either from its own expansion or from impulse conveyed to it by the throbbing, small artery, the complete absence, as yet, of pulsation and bruit may be accounted for. The same explanation would account for the absence of any serious symptoms of pressure on the ophthalmic vein or other structures. Of course this theory of the case must as yet be considered as open to question. The characteristic symptoms may yet be developed and make the case clear. My opinion, however, is so strongly in favor of an arterial lesion, that I believe that the symptoms can be relieved by systematic pressure on the carotid. As the patient is present, it gives me great pleasure to submit him to the Section for examination. I can only say that with one exception the symptoms are to-day what they were three weeks ago. The tension of the globe is now *minus*. It was not so then.[1]

[The patient was then presented.]

In conclusion, I will sum up the symptoms which seem to justify the diagnosis of true intra-orbital aneurism, as follows:—(1) If traumatic in origin, the nature of the injury. If it is by direct penetration of the orbit by a long, slender body, or a small shot or similar foreign substance, the ophthalmic artery may have been wounded, as was probable in one of my cases. (2) If the injury to the head or face, though severe, is not attended by symptoms of fracture of the base of the skull, or, in the absence of the positive symptoms of fracture, if the severity and character of the trauma are not such as to make such a lesion probable. (3) The strictly rhythmical character of the pulsations, if such exist. (4) The limitation of the region over which the bruit is heard, to the eye and orbit. (5) The strictly intermittent character of such bruit. (6) The fact that the patient himself does not hear the *souffle*, or, if so, very slightly. (7) The less frequent occurrence of paralysis of motion or sensation, or of any symptoms indicating a disturbing cause in the cavity of the cranium. (8) The less frequent and less serious impairment of vision. (9) The absence, except at an advanced period, and even then the less intensity, of the symptoms of obstruction in the ophthalmic vein, such as the existence of soft, thrilling, pulsating tumors around the eye, and of enlarged and pulsating frontal veins. (10) The complete curability of the disease by direct compression through the eye; or by compression of the common carotid; or by ligature of *one* (the corresponding) carotid.

The symptoms, till recently, accepted as characteristic of intra-orbital aneurism, are much graver and more extensive in their distribution. When we submit them to the test of pathological anatomy, as far as such cases have been examined, it is seen that they depend on lesions

[1] This patient was seen again on April 15, 1877, when there was great protrusion of the eyeball with aggravation of all the other symptoms; a tumor could now be felt behind the globe. Enucleation of the eyeball was resorted to, when the tumor, which was firm and fibrous in character and the size of a small pullet's egg, was readily removed. It was situated between the optic nerve and the inner wall of the orbit, but was not firmly connected with either. (July 5, 1877.)

beyond the orbit. Of the 73 cases reported in Mr. Rivington's paper, in 12 only were autopsies made. Some of Mr. R.'s conclusions I will quote: "In no single instance has aneurism by anastomosis, or cirsoid aneurism within the orbit, been verified by post-mortem discovery." "In no single instance has an arterio-venous aneurism been found within the orbit at a post-mortem examination." "In no case have the symptoms of intra-orbital aneurism been proved to be due to a tearing across of the ophthalmic artery at or near the optic foramen." In the case of Guthrie, an aneurism was actually found in each orbit. In one case, no arterial lesion was found, but partial obliteration of the orbital veins, with evidences of previous inflammation in the orbital tissues. In the other ten, in which autopsies were made, the symptoms were caused by disease of the vessels just back of the orbit, in the cavity of the cranium. Of these, some were dependent upon obstruction to the return of the venous blood from the orbit to the brain. In one a small aneurism existed on the ophthalmic artery at its origin from the internal carotid. In three there was rupture of an aneurism of the internal carotid, within the cavernous sinus. In one, "simple dilatation and atheromatous degeneration of the internal carotid artery in the cavernous sinus." "In three, traumatic cases, a direct communication between the carotid artery and the cavernous sinus was found."

Finally, a word as to treatment. Compression, either direct, or of the common carotid, or both, is advisable in all cases, and succeeds in some. Coagulating injections may sometimes be successfully practised, but require great caution. And finally, ligation of one or both carotids will be nearly always necessary for the extra-orbital cases.

SPONTANEOUS CURE OF CONGENITAL PULSATING EXOPHTHALMOS.

BY

GEORGE C. HARLAN, M.D.,

SURGEON TO WILLS HOSPITAL, OPHTHALMIC AND AURAL SURGEON TO THE CHILDREN'S HOSPITAL, PHILADELPHIA.

THIS case was reported at the last meeting of the American Ophthalmological Society, but since then the aneurismal tumor has spontaneously undergone complete consolidation. The following abstract of the history, to date of last report, is taken from the transactions of the society referred to:—

L. L., æt. 25. General health good. Left eye always prominent, and left side of head larger than right. Has always had a "rushing sound in his head and eye." Left eye enormously protruded, forced downwards and outwards, and immovable. No useful vision. Whole left side of face hypertrophied. Mucous membrane of left side of mouth thickened, and left side of tongue twice as large as right. A localized tumor, probably a distended vein, above and to inner side of ball, and a doughy swelling of the soft parts extending about an inch above the orbit. There was strong pulsation, and an aneurismal bruit could be heard several feet from the patient's head. Five years after the first examination, the protrusion had slightly increased, but the bruit had decidedly diminished. The supra-orbital and frontal vessels were much distended, and pulsated strongly, and this aneurismal condition extended down the angular branch of the facial, on the right side.

On December 27, 1875, the patient came to me, complaining of pain in the eye, and over the bridge of the nose, and along the course of the angular artery on the right side. There was slight erysipelatous inflammation at the seat of pain, but not much change in the appearance of the parts. The bruit had entirely disappeared, and there was no thrill in any of the vessels, and no pulsation anywhere except in the localized tumor above the ball. The supra-orbital vessels were scarcely perceptible. He had not been under any treatment, as he was not able to keep up even occasional, intermittent compression of the carotid, on account of the giddiness and faintness which it produced. The continuous application of iced water was directed.

December 31. There was violent pain in the tumor and head. The tumor was increased to at least twice its former size. Pulsation was just perceptible. The exophthalmos was enormous, and the eye could no longer be covered by the distended lids. The patient was admitted to Wills Hospital, and anodynes were given in large doses, and dry cold substituted for the iced-water applications.

January 2, 1876. The pain was somewhat relieved, and all trace of pulsation in any part of the tumor had disappeared. The cornea was completely anæsthetic, and was beginning to slough. The pulse was feeble, and the pulsation of the left carotid was weaker than that of the right. From this time the pain and swelling gradually subsided, and

when the patient left the hospital, on February 2, the tumor was completely consolidated, and had considerably diminished in size.

No satisfactory way of accounting for this sudden and unlooked-for termination of the disease suggests itself to my mind. It is interesting as illustrating the possibility of spontaneous cure under circumstances that would seem to be about as discouraging as possible, and suggests the inquiry, what percentage of cases, if let alone, might end in the same way? This question cannot be answered, as nearly all reported cases have been subjected to some kind of surgical treatment.

I find records of five other cases of spontaneous cure, all but one having been of traumatic origin.

Case I. Collard; quoted by Erichsen (Science and Art of Surgery, American Edition, 1869, p. 643). A man, 41 years of age. Injured by fall on back of head. Bruit, pulsation, exophthalmos. Symptoms entirely disappeared in three years and a half.

Case II Erichsen (Ibid.). Man, 44 years of age. Fall on head. Attacked by symptoms of aneurism of left orbit in most marked manner. Bruit, pulsation, exophthalmos. Ligature of carotid urged by Mr. Erichsen but declined by patient. At the end of fourteen months the symptoms had, to a very great extent, disappeared.

Case III. Holmes (American Journal of the Medical Sciences, July, 1864). Man, 23 years of age. Gunshot injury. Exophthalmos, chemosis conjunctivæ, bruit, pulsation. In about three months all the symptoms had entirely disappeared, except slight congestion of the conjunctiva.

Case IV. France (Guy's Hospital Reports, 1853). Woman, 38 years of age. Point of umbrella thrust into orbit. Exophthalmos, pulsation of eyeball, and defined, pulsating tumor above and to inner side of globe; complete blindness. All the symptoms but blindness disappeared in eight months.

Case V. Julliard, of Geneva ("Note sur un Anévrisme Intra-orbitaire, etc.," quoted by Rivington, Medico-Chirurgical Transactions, London, vol. lviii. p. 272). Woman, 69 years of age. Spontaneous. Enormous exophthalmos, pulsation, bruit, chemosed conjunctiva. In two months all the symptoms but exophthalmos and blindness had disappeared. A few months later, the exophthalmos was also gone.

In none of these cases was any local treatment resorted to, except that in two or three instances cold applications were employed in the early stages. In connection with the case reported to the Section by Dr. Williams, and that now submitted, they make a total of seven instances of spontaneous cure of this affection.

Though statistics prove beyond doubt that ligation of the carotid affords the largest percentage of cures, it is well, before deciding upon its performance, to remember not only the possibility of cure by milder means, or even without resort to any surgical procedure at all, but to bear in mind also that, though one of the most brilliant operations in surgery, it is not without its chances of failure and its dangers of a fatal result. All the operations that I have been able to collect, including two of Dr. T. G. Morton's, not yet reported, furnish sixteen per cent. of deaths and about the same proportion of failures, leaving only sixty-eight per cent. of cures and partial cures.

ARE PROGRESSIVE MYOPIA AND CONUS (POSTERIOR STAPHYLOMA) DUE TO HEREDITARY PREDISPOSITION, OR CAN THEY BE INDUCED BY DEFECT OF REFRACTION ACTING THROUGH THE INFLUENCE OF THE CILIARY MUSCLE?

BY

EDWARD G. LORING, Jr., M.D.,

OF NEW YORK.

After a careful consideration of the above question, I have come to the conclusion: (1) That hereditary predisposition, though undoubtedly a potent cause, is not only not the sole cause, but not even the predominating cause, of progressive myopia; and (2) That the action of the ciliary muscle, taken by itself, exerts but little influence on the production of myopia, and still less on the formation of the cone.

The arguments on which these conclusions are based will be found in the following remarks:—

The belief that "like begets like" has been formulated in the speech and crystallized in the proverbs of every people since the world began, and although this uniformity of opinion exists as to hereditary predisposition, and its influence on the organism in general, a great deal of doubt has been expressed as to the degree of effect which it produces on particular and individual organs, and especially on those which fulfil the functions of special sense. Nor can it be doubted that grave objections have from time to time been raised, and many weighty arguments advanced, which would go to show that the effect of direct transmission could not be so readily detected, nor so clearly demonstrated, in regard to the special senses as to the organism as a whole. Still, in later years, as proofs have gradually multiplied and apparent discrepancies have been reconciled, the opinion has gradually become more general that, beneath a mass of apparent contradictions and almost endless exceptions, there lies a general tendency of inheritance which authorizes us in assuming that even with our special faculties there is a uniform, though perhaps, from want of knowledge, a rather flexible, law, which controls, to a degree at least, their form and character.

In none of these is it claimed that this law of transmission is made more manifest than in sight, the noblest and most intellectual of all our faculties. Thus it has been assumed by the preponderance of authorities, that the specific type of the organ of vision has its varieties of form and perception, every one of which may owe its origin to the force of heredity. Thus it is held that color blindness, strabismus, hypermetropia, and myopia, are transmissible by generation, so that according to Lucas(1)[1] there are families among which many of their members owe

[1] The numbers attached to the names of the authors refer to the bibliography at the end of the paper.

to hereditary influences alone the conformation of their optical apparatus, and the fact of their range of vision being short or long. It is further claimed that the statistical results of Funari(2), supported by the statements of Piorry(3) and Portal(4), have shown that most myopes are the sons or grandsons of myopes. It is certainly not necessary for me to remind the members of this Section that views, similar to, if not identical with, those just quoted, as to the hereditary tendency of myopia, have held sway successively in England, France, Germany, and in this country, and indeed in every country. Nor would the time allotted to this paper allow me, even if your patience would, to cite the long list of distinguished names through whose authority this wide-spread opinion has had and still has its existence; still, for the sake of the arguments which are to follow, I should like to be allowed to refresh your minds in regard to the opinions of a very few of those who in our own time have done so much towards moulding the prevailing opinion as to the hereditary nature of myopia.

Thus Stellwag von Carion(5), in discussing the causes of myopia and the elongation of the eyeball, says "the predisposition to this is of course congenital, and is, as a rule, hereditary," and adds, in speaking of the staphyloma and its relation to the scleral protuberance, that the "exquisitely hereditary character of the affection can also be brought forward as a proof of this." Jaeger(6), while emphasizing the fact that myopia is not the "prerogative of industry," declares that "posterior staphyloma is hereditary to a predominating degree." And Donders(7), in speaking of the causes of myopia, affirms that "the predisposition is almost always congenital, and in that case it is, moreover, nearly always hereditary. Beer, Jüngken, Bohn, Von Hasner, and many others, have referred to its hereditary nature, and I believe even that from time immemorial the conviction thereof has been general among the people." Many more examples quite as explicit as these might be cited here, were it necessary, since, as you are well aware, every standard work on ophthalmology is replete with them.

It would be supposed, from the force of the expressions and the weight of authority from which they come, that these opinions in regard to the predominating influence of heredity in myopia would be based on exact and extensive statistical information which would embrace, certainly, as wide a scope as from grandfather to father and from father to son. Yet, as far as I am aware, no such statistics exist, at least of such a nature as to satisfy the exacting demands of modern science. It is very true that both Donders and Jaeger have—as indeed we all have—been struck with the frequency with which myopic parents bring to us their myopic children; but, as you are well aware, the mind, in these matters, is more prone to be struck with resemblance than with dissimilarity, and no account is taken or recorded anywhere, as far as I know, of how often the reverse holds good, that is, how often children with myopia are brought by parents who, on actual examination, are shown to have normal eyes, and whose ancestors on both sides, as far as known, were never near-sighted. Moreover, I found that among 715 well-educated and intelligent persons, whom I examined for this special purpose, the percentage of those who had normal eyes themselves, but whose parents were myopic, was nearly identical with the percentage of those who were not only myopic themselves, but who had myopic parents. That is to say, that the percentage of emmetropic children from myopic parents was as high as that of myopic children from myopic parents. No one more fully

recognizes or more freely admits than I the liability to error in statistics gathered thus as it were at second-hand. Nothing but the tabulated observations of three generations at least can be of much value as regards heredity, but as such do not exist, I offer the above for what they may be worth.

These observations would, however, seem to be in accordance with those of others. Thus Cohn(8), in his investigations as to the refraction of the eyes of school children, found that out of all the myopes there were only 2.7 per cent. whose father or mother were myopic. I found that only 6.11 per cent. had either father or mother near-sighted. With both parents myopic, the percentage falls with Cohn(9) to 1.04 per cent. and with me to 1.11 per cent. Erismann(10) found, however, from his statistics that 30.6 per cent. of the myopes had one or both parents myopic. Taking, then, Erismann's percentage, which is an enormous increase over Cohn's and mine, as a basis, we find, even then, that two-thirds, or seventy per cent., of the myopic children had parents who were not myopic. This certainly does not show, as far as statistics are concerned, a marked hereditary tendency, or warrant, it would appear, the expression of so decided an opinion as that which we have quoted from the leading authorities.

There are, however, in the absence of exact statistical knowledge, several factors of less importance, it is true, but still of sufficient force to aid us materially in the solution of the problem, and amongst these the most important are necessarily those of an anatomical nature. For if in any case of disease it can be shown that an anatomical formation is peculiar to a certain disease, the presumption is that it is congenital as a rule; and the earlier it shows itself the more likely is it to be hereditary. That both of these conditions have been fulfilled in regard to myopia by the change known as posterior staphyloma, is almost universally admitted. Thus Stellwag(11) declares that posterior staphyloma is due to congenital malformation, while Jaeger(12) says that "the increase in the axis is usually accompanied with a cone which is mostly congenital, and frequently hereditary," and adds that he has seen "typical cases of it in the eyes of new-born children both in life and after death;"(13) and Donders(14) only strengthens the almost universal opinion when he declares that from the frequency with which changes in the bottom of the eye have been observed with the ophthalmoscope, myopia and staphyloma have become nearly synonymous terms. This statement he supports by a reference to Graefe(15), who had previously declared that, in myopia of $\frac{1}{6}$ to $\frac{1}{2}$, ninety per cent. showed that peculiar change in the fundus, and adds that he himself(16) believes the proportion is much nearer one hundred per cent. Still there can be but little doubt that the general and rather sweeping assertion that posterior staphyloma is synonymous with myopia, is somewhat exaggerated. For out of 500 myopic eyes I found only 20.5 per cent. affected with the crescent. Cohn(17) in 1004 cases of myopia, between the same ages, that is, from 6 to 21 years, found the cone present in only 20 per cent.; while Max. Conrad's(18) examinations in 1001 myopes showed 28.1 per cent. The average of these results would then show that only 22.3 per cent. of myopic eyes have the cone. Of my own cases there were only one-fourth which showed any change whatever, while there were three-fourths of the eyes which showed no deviation from the normal standard. This is certainly at variance with the accepted views, though it is corroborated as seen above by the extensive statistics of Cohn and Conrad, the unanimity between the results being

very remarkable. When, however, we come to the proportionate frequency of the cone in regard to the three classes of refraction, we find that it predominates to a marked degree in myopia. Thus I found of 2265 eyes examined, that of the emmetropic eyes 3.33 per cent. had cones more or less developed; of the hypermetropic 3.49 per cent.; while in the myopic the percentage rose to 20.56 per cent., or six times as much as in either of the other classes. We are forced to conclude, therefore, that there is an anatomical variation predominating in myopic over other eyes, although the frequency with which it occurs has been, it would appear, much overrated—certainly for this country. Still, too much weight should not be put upon this fact as an argument as to the congenital and hereditary character of the cone, since, in the first place, an anomaly which makes its appearance in only about one-fourth of the cases, and under the most favorable auspices for its development, that is, in school children between the ages of six and twenty-one years, cannot be said to be strongly congenital.

Moreover, it is a fact that, although, as stated by Jaeger(19) and Von Hasner, well-marked cones are found in new-born children, they are, as known to all, and admitted by them, comparatively rare; while they increase in frequency in after life, and with close application; and oftentimes in eyes which have been shown by repeated ophthalmoscopic examinations to have been previously free from the slightest trace. From these facts, and from the fact that myopia consists as a rule simply of an elongation of the globe, which would, from purely mechanical reasons, produce a crescent, a doubt has arisen, in my own mind at least, whether after all the cone was an expression of congenital malformation of the scleral protuberance, or indeed of any part of the scleral split.

For, if it had any connection with the split, we should suppose it would be in reality what both its name and alleged anatomical origin imply, that is, an actual protrusion of the sclera, or at least an excavation or limited thinning of this membrane, as is invariably the case with a true coloboma, as demonstrated as well by the ophthalmoscope as by dissections. But I hardly need remind those of you who use the upright image that there is almost never the slightest difference in level between that part of the sclera which represents the cone and the adjoining portions, and this, too, no matter how large the crescent is. The cone is, in fact, not a true staphyloma; and it is only when applied to the entire posterior portion of the eye that the name is at all applicable, and we should be forced to assume that the whole posterior part of the eye was congenitally defective, or at least that parts were so which were widely separated from the scleral protuberance.

The second anatomical variation which is supposed to be characteristic of the myopic eye, and one which has had great importance attached to it, is the peculiar conformation of the ciliary muscle, which is supposed to be congenital. From the labors of Iwanoff(20) it was shown that the ciliary muscle in highly myopic eyes varied from that in other eyes, not only in general outline, but also in its composite structure. In the drawing (Fig. 1), which is taken from Iwanoff, the shape and outline of the muscle in the three classes of refraction are contrasted with each other. The solid line represents the muscle of an emmetropic, the dotted that of a myopic, and the broken line that of a hypermetropic, eye. It will be seen that the muscle in the myopic eye extends further back along the sclera than in the normal eye, and is, moreover, broader. It will be observed also that the short side, or leg, of the triangle, which repre-

sents the muscle as a whole, forms in the normal eye nearly a right angle with the sclera, while that in the myopic eye forms an acute angle, with the apex towards the inner portion of the eye. As to its component parts, it was shown that the circular fibres found in the normal eye were

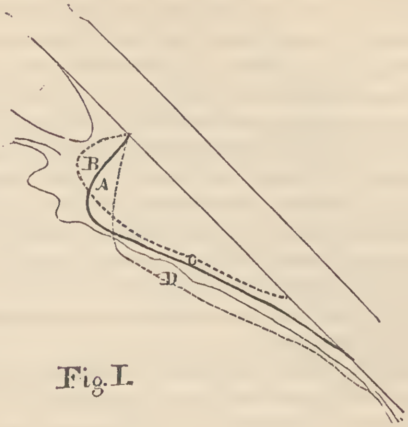

Fig. I.

either very much reduced or entirely wanting in the myopic eye, while they were increased in the hypermetropic eye. It was, therefore, assumed that, inasmuch as the myopic eye from its structure had no demands for active accommodative efforts, the reason why the circular fibres were not present was because they had become atrophied from disuse, so that the entire triangle marked A had disappeared. While, on the other hand, the circular fibres had been so increased by active accommodative demands in the hypermetropic eye as to occupy the superadded triangle B. It was further shown by Iwanoff that not only had the circular fibres become atrophic, but that the longitudinal had become hypertrophied. From this it was assumed that the action of the muscle had been changed, and that, instead of being compound, the circular fibres drawing toward the axis of the eye while the longitudinal drew directly forward, the action had become solely the latter, so that the muscle had become what the author calls a pure "tensor choroideæ." If we should accept this theory, we would have the apparent *reductio ad absurdum*, as the author himself says, in the development of a force which he supposes to produce active accommodation, in an eye which does not require or use it; for traction on the choroid and consequent relaxation of the zonula is supposed by Helmholtz and other physiologists to be the important element in the production of accommodation.

It would certainly lead me too far to enter in a discussion of this subject, but it seems as if a very important factor, and one which might produce a marked effect on the form and shape of the muscle in the myopic eye, had been neglected in the consideration of this question. This is the effect of distension of the investing membranes of the eye, which in some cases is enormous, as, for example, where progressive myopia is developed very rapidly and to a very high degree. It would, therefore, certainly seem more natural to attribute the change in form and structure to this than to any difference in function of its component parts. Thus if the posterior pole of the eye should yield, the insertion of the muscle at its choroidal end would be drawn back as seen in the drawing, and the angle

which, as we have seen, was a right angle in the normal eye would then become acute, since the insertion around the canal of Schlemm and adjacent parts would remain stationary. The few so-called circular fibres which form an anastomosing network, whose meshes run more or less perpendicular to the direction of the longitudinal fibres, would on being stretched assume precisely the opposite direction, and would then have on section the same general direction as the longitudinal, as would of course also the so-called radiating, fibres. Moreover, as the horizontal and vertical diameters also increase somewhat in these highly myopic eyes, the zonula would be stretched, and would then draw with a gentle but sustained traction on the muscle, the general direction being perpendicular to the axis of the eye. Thus the fibres of the muscle would have a tendency to draw apart, and the muscle to increase in bulk. This tension on the zonula would also account for the fact that the lens is flatter in high degrees of myopia than in the normal eye. Thus appearances hitherto supposed to be congenital might occur from a simple mechanical cause, acting during life in an eye which was not congenitally myopic, and with no hereditary tendency.

Thus while not denying the hereditary tendency towards a too yielding sclera, I have become more and more convinced that there are many cases in which the cone is simply the expression of a purely mechanical effect, distension, from which all the peculiar appearances of the crescent might result without there being the slightest connection between the cone and any congenital or hereditary tendency whatever. Does the inguinal ring never give way, or the fibres of the bladder become relaxed, or the pleura distended, or ascites occur, or even the bony cavity of the head enlarge, except through hereditary tendency? and if these can owe their origin, as they often do, to exciting causes which are purely spontaneous and fortuitous, why may not that distension of the sclera, which is myopia, take place, especially when the growing and elastic membrane is subjected to over-use, without our being compelled to attribute it "almost invariably to congenital and hereditary influences?" Clinical experience would point to such a conclusion, for it is a fact that cases occur where myopia with all its characteristic signs is produced in eyes which were previously normal; that is, in the eyes of adults, who have passed therefore the period of development, and whose family history shows no hereditary tendency. This, too, notwithstanding Donders's(21) assertion that he has never seen "myopia arise after the twentieth year in eyes which were previously normal." I have seen several such cases, and I doubt not that most practising ophthalmologists have had the same experience.

If this distension of the sclera did take place, there would be, necessarily, a change in the refraction of the eye, and this would have a decided weight in determining the question of hereditary influence. For if it could be shown that normal eyes which, according to the theory of heredity, would presuppose normal, *i. e.*, emmetropic, ancestry, or better still if it could be shown that hypermetropia, the direct opposite of myopia, with the opposite hereditary tendency, could and did frequently pass into myopia, then it would be an almost convincing proof that myopia could be and often was produced in spite of hereditary influence against it.

That an emmetropic eye can and does pass into a myopic eye, and that it has been proved to do so by direct observation, I think will be admitted by the great majority of observers. But that a hypermetropic

eye can pass into an emmetropic or normal eye, and thence into a myopic eye, is still a matter of great doubt in the minds of some of the best authorities. Thus Donders(22) says: "I have never seen a hypermetropically constructed eye become near-sighted." An opinion which he corroborates and strengthens in many other passages in his world-renowned book. Jaeger(23), however, makes a diametrically opposite statement, and declares that an interchange of refraction does take place, and that "thus an hypermetropic as well as a normally-constructed eye becomes a myopic eye through posterior staphyloma at the posterior pole of the eye." Stellwag(24) proclaims the same thing in very nearly identical terms. Various authorities too numerous to mention have ranged themselves on one side or the other of these opposite opinions, though I think that the majority of the more modern observers are tending towards the view expressed by Jaeger, that an interchange of refraction from a hypermetropic to a myopic eye can and does take place. Still it must be admitted, when it comes to actual demonstration, that the few cases which have thus far been cited are not sufficient in number or accuracy of detail to be of the slightest weight. One would certainly suppose, *à priori*, that such cases would have been observed in great numbers, and the fact that they have not, in the past decade when refraction has been so minutely studied, would seem to point very strongly to the fact that they did not exist.

In the dearth, therefore, of sufficient direct proof by observation of the passage in the same person of emmetropia into myopia, and the almost total want of such evidence of change in hypermetropia, we are forced to the consideration of collateral evidence which, it appears to me, if correctly taken and properly appreciated, is nearly as convincing as that of actual observation. I allude to the proof furnished by statistics taken from large masses of individuals, which show the proportionate rate in which the different classes of refraction occur at different times of life, and with different degrees and kind of application of the eyes. From the statistics of Ware(25), in 1813, and in later years from those of Szokalski(26), Schürmayer(27), Jaeger(28), Ruete(29), and others, very important facts were obtained. Thus it was shown by Ware that myopia was more common in cities than in the country, and that it increased in frequency and in degree with the age and amount of close application, while Ruete also called attention to the deleterious effect of insufficient and faulty illumination. These facts were afterwards corroborated by Cohn, but unfortunately Cohn's statistics, extensive as they are, are not suitable for our purpose, since, from the manner in which they were compiled, no correct idea can be obtained from them as to the frequency with which, in comparison to each other, the three different classes of refraction occur.

The statistics to which I shall call your attention are those made by Erismann(30) in Russia, Max Conrad(31) in Germany, and those by Dr. R. H. Derby and myself in this country. I choose these as examples since they are the only ones which I know of where sufficient numbers were used, and where, at the same time, the conditions of investigation were the same, or nearly the same, in each. Thus they were all upon the eyes of school children between the ages of six and twenty-one years, and the trial by glasses and Snellen's type at twenty feet were the basis of the examination; while all the more commonly occurring degrees of refraction from the lower ($\frac{1}{60}$) to the highest grades were included. Every eye was examined by the ophthalmoscope in the cases reported by Dr. Derby

and myself. Erismann's statistics were made in St. Petersburg on the eyes of 4358 scholars; Conrad's at Königsberg on 3036 eyes, and Dr. Derby's and mine on 2265 eyes in New York. The results of these statistics are arranged in a tabular form in the diagrams marked respectivly

Table I.

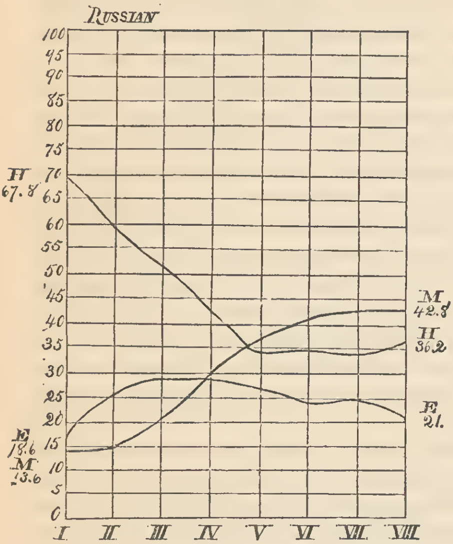

Table II.

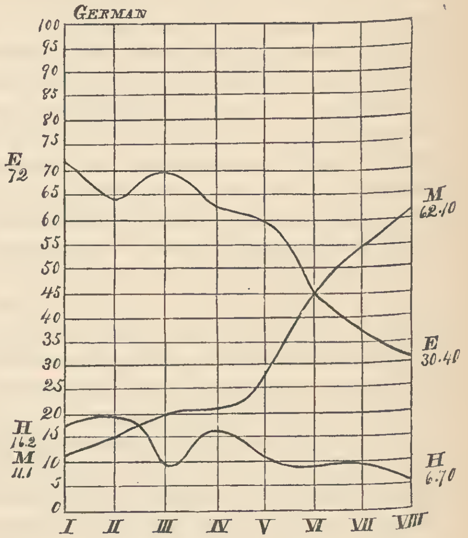

Russian, German, and American, Tables I., II., III. The numbers at the foot of each chart represent the progression of the classes from left to right, that is, from the lowest to the highest, or, what is the same thing,

Table III.

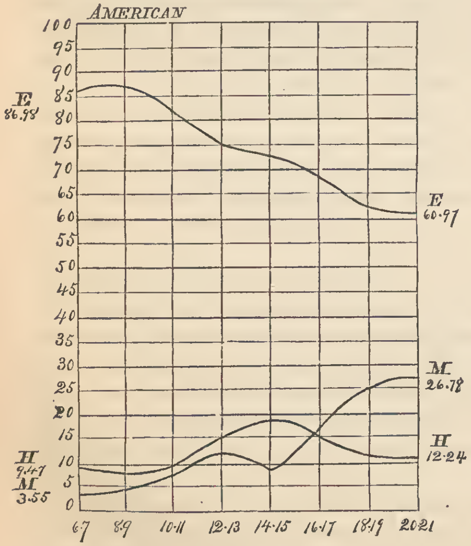

Table IV.

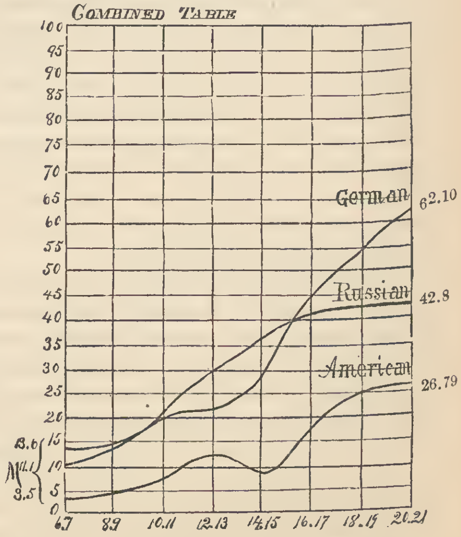

from the youngest to the oldest, as in the American diagram. This last is made necessary from the fact that the arrangement of the classes differs in this country from that in the foreign schools. Since, however, the successive classes correspond almost exactly to the successive ages, this can make no practical difference, especially as both the Russian and German statistics were calculated in both ways, and no material variation found between the results of the two methods. As it is the result of the entire school term, that is from six to twenty-one years, which now interests us, and which is the same in all countries, the comparison between the different nations is a just and fair one.

The numbers running longitudinally on the diagrams show the increase and decrease in percentage, each of the larger spaces representing ten, and each of the subdivisions five per cent. The line marked E represents the curve which emmetropia takes in the different years, M the myopic and H the hypermetropic curve. It will be seen on inspection, that, however much these curves differ in degree in the different diagrams, and amongst themselves, they all show that the refractive power increases with the advance in life.

Thus in the Russian diagram the frequency in which H occurs diminishes from 67.8 per cent. in the lowest class to 36.2 per cent. in the highest, while M increases from 13.6 per cent. to 42.8 per cent. Emmetropia increases a little, from 18.6 per cent. to 21 per cent. In the German[1] diagram, H descends from 16.2 per cent. to 6.70 per cent.; M rises from 11.1 per cent. to 62.1 per cent.; while E decreases from 72 per cent. to 30.40 per cent. In the American diagram, H rises from 9.47 per cent. to 12.24 per cent.; M rises from 3.55 per cent. to 26.79 per cent.; E sinks from 86.98 per cent. to 60.97 per cent. It will be seen from the Russian diagram that the emmetropia remains about the same through the entire series of classes, while the myopia steadily increases. If we assume that this increase, which is equal to 29.2 per cent., is due to emmetropia passing to myopia, we are forced to assume that the balance is maintained by hypermetropia passing to emmetropia to supply the deficiency. According to this diagram a part of the hypermetropia must become emmetropia, and if a hypermetropic eye can become emmetropic by increasing its refraction, it would be absurd to deny that it could not, by a little further increase, become myopic. So too in the German diagram it is seen that the increase in myopia, which equals 51 per cent., is greater than the decrease of emmetropia, which is 41.60 per cent., that is, is greater by 10 per cent. It must consequently have taken this increase from the hypermetropia, which is indeed seen to have decreased 10 per cent. From the American diagram it will be seen that the emmetropia decreases 26 per cent., while the myopia increases only 23 per cent., so that in this case the myopia may have been derived from the emmetropia alone. The slight increase in the hypermetropia may be explained by a small amount of latent H becoming manifest as the age advanced. The increase in refraction, however, though not so great as in the other two diagrams, is nevertheless very marked. It will, moreover, be seen in both the Russian and German diagrams that, while the lower grades of refraction E and H predominate

[1] Conrad also gives a separate curve, as determined with the ophthalmoscope. For the sake of simplicity and uniformity in the diagrams I have omitted this curve, and taken only those which were determined with glasses. The increase in refractive power is, however, more marked with the ophthalmoscope than with glasses. Still I cannot persuade myself that it is, on the whole, as accurate with the instrument as with test types.

in the lower classes, a complete change occurs, and M becomes the predominating refraction, and that this change takes place at a comparatively early age. Thus in the Russian diagram the line M crosses the line E at the fourth class, or what would correspond on the American diagram to the years 12–13. It crosses H at 14–15, when myopia becomes the predominating refraction, being in the highest class twice as frequent as the normal eye. Precisely the same thing occurs in the German diagram, where M, rapidly rising, crosses both H and E, being in the highest classes twice as common as the normal eye. In the American diagram, however, E remains all through by far the predominating refraction, the line E not only never crossing those of H or M, but remaining at a distance amounting at its lowest point in respect to M at its highest, to 34 per cent., and in respect to H at its highest, to 43 per cent.

This would show, if the numbers were great enough to prove it, and I think they are, that not only is there less myopia in this country in school children than in either Russia or Germany, but that emmetropia is the normal eye in all classes, which agrees with what Donders(32) found among the Dutch. For it may be assumed that after the age of twenty-one the refraction as a grand whole changes but very little, and that any slight change towards myopia in early adult life is more than counterbalanced by acquired hypermetropia in later life. Moreover, as we have taken as a standard the very class where myopia would be most frequent, that is in over-worked school children, it is fair to assume that the proportion of myopia would be less and not greater in other classes, especially in the lower and middle ranks of life. In order to make a better comparison between the three nations, as far as the myopia is concerned, the myopic curve of the three preceding tables has been transferred to a separate diagram, Table IV.

As an additional means of estimating the effect which the hereditary influence has on myopia, a comparison was made as to the frequency in which myopia occurred in the three principal nationalities of which our public schools are composed, that is, among the pupils of German, American, and Irish parentage. It was found that of all the German scholars 24 per cent. were myopic, of the Americans 20 per cent., and of the Irish 15 per cent.; so that even in this country, and under the same school influences, myopia occurs more frequently among the descendants of Germans than among either the Americans or Irish. The comparatively low percentage of myopia among the Irish is certainly remarkable. It is, however, in accordance with the assertions of various authors as to the immunity from myopia among the inhabitants of Great Britain. There can be no doubt that as a nation the Germans show a strong tendency towards myopia. Whatever may be the cause of the trouble, it is certainly a fact that the statistics of myopia taken in German schools show a decided increase over those taken in this country, which can be seen by comparing the statistics taken by Dr. Cheatham(33) in New York, by Dr. D. B. Williams(34) in Cincinnati, and Drs. Prout and Mathewson(35) in Brooklyn, with those taken in Germany. In comparing these statistics the different basis on which they are compiled should be taken into consideration, especially with those of Cohn, as he did not include myopia less than $\frac{1}{36}$, while in those cited above and made in this country $\frac{1}{60}$ was included.

From the evidence furnished by such statistics made in different countries and by different observers, I do not, while admitting the hereditary tendency, see how we can exclude the fact that there are many eyes

which, under prolonged tension of the accommodation, pass from hypermetropia to emmetropia, and thence to myopia with all its attending signs and symptoms, and this too in spite of hereditary influence to the contrary.

This factor of prolonged tension of the accommodation brings us at once to a consideration of the second proposition of our subject, which is whether posterior staphyloma and progressive myopia can be produced through the influence of the ciliary muscle. Before proceeding to discuss this, I would call your attention to the fact that the question does not refer to the entire act of accommodation, which implies the action of the recti muscles as well as that of the ciliary muscle, but is limited to the latter alone, and consequently I am desirous that it should be kept in mind that my remarks are confined to the share which the ciliary muscle alone takes as an agent in the production of myopia and the cone. There are two ways by which the ciliary muscle could render an eye previously not near-sighted, myopic. The first would be by increasing the curvature of the lens by active, that is, positive, contraction; and the second, by producing an elongation of the antero-posterior axis. That such an increase in curvature of the lens does, by contraction of the muscle, take place, with the effect of temporarily increasing the refraction of the eye, is now universally admitted. The only question which interests us here is whether the increased curvature of the lens through the agency of the ciliary muscle ever becomes permanent, and thus transforms an eye from an emmetropic or hypermetropic to a myopic eye. That such was the opinion of the earlier oculists I need not remind you, down even to the time when Cramer declared that there were myopic eyes in which the curvature of the lens corresponded to that in the normal eye when adjusted for near objects. Nor need I dwell on the revulsion of feeling which followed when it was learned from the labors of Helmholtz, Knapp, and Donders, that this last fact was not correct, and that the curvature of the lens in myopic eyes was shown to be if anything less than in the normal eye. A revulsion of opinion which culminated in Donders's(36) declaring, though formerly a firm believer in its occurrence, that he had never, since the true nature of refraction had been understood, been compelled to resort to an increased curvature of the lens as an explanation of myopia, while Giraud Teulon declares that there never has been a single well-authenticated case put on record.

The opinion that myopia is never due to increased curvature of the lens, has, however, been combated from the first by a few of the very best authorities, especially by Jaeger(37), who declares that "frequently the sole cause of myopia is the increased curvature of the lens," and by Stellwag(38), who in his last edition affirms that "increase in convexity of the lens is indisputably an important pathogenetic cause of short-sightedness;" and it cannot be doubted that this opinion, certainly as regards the initial cause of myopia, is gaining ground among the younger school. Still, notwithstanding the plausibility of the theory that increased curvature of the lens causes myopia, there is, it must be confessed, but little actual proof of its existence from such a cause. Indeed it must, I think, be admitted that the proof both experimentally and clinically points just the other way. Thus experimentation shows that by actual measurement the curvature of the lens is less if anything in a myopic than in a normal eye. Then comes the great clinical fact that in those cases of hypermetropia of a high degree, proved to exist in young children who are watched from year to year, the amount of the *total* hypermetropia does not decrease under

accommodative efforts, while the manifest does increase year by year in spite of such efforts. Thus the patient is compelled to go, not from stronger to weaker glasses, but from stronger to stronger, in spite of every effort to maintain the former amount of curvature of the lens. The very frequent occurrence, too, of adults with very high degrees of hypermetropia, who have been straining their ciliary muscle to the utmost for years to overcome their optical defect, is decidedly against the view that the curvature of the lens becomes permanently increased by over-tension; as is also the fact that in high degrees of hypermetropia where there is little or no manifest, the total is revealed by the ophthalmoscope, and then coincides with an amazing exactness with that produced by the full effect of atropine. Such facts as these, and many others might be quoted to sustain them, warrant us in the belief, until more convincing proof to the contrary is offered, that as a rule the action of the ciliary muscle has no effect in producing a permanent increase of curvature of the lens, and thus becoming a cause of myopia—no matter what the original condition of refraction. In regard to the second point in our investigation, that is, whether the ciliary muscle is capable of producing an elongation of the axis, thus causing myopia, it will be sufficient to call to mind that Young's(39) and Helmholtz's(40) investigations prove the impossibility of such a result.

But it may be urged—as, indeed, it has been frequently, especially since Dobrowolsky's(41) investigations—that, even if the natural, or what may be called the tonic, contractions of the muscle, do not produce myopia by directly increasing the curvature of the lens, spasmodic or clonic contractions do; and that the myopia first produced by increased curvature of the lens is followed by irritation of, and traction on, the deeper-seated membranes, which lead to true myopia—that is, to an elongation of the axis. If this were so, we should expect to find the signs of irritation more frequent where the strain of the ciliary muscle was the greatest—that is, in hypermetropic eyes. But it is an undeniable fact, as pointed out by Donders, and confirmed by every observer with the ophthalmoscope, that the injection of the nerve and the signs of irritation are not any greater than in the normal eye. Moreover, we should find, if simple traction on the choroid could produce the cone, that these would be most frequent where the traction of the muscle was the greatest; and this, too, independently of any increase of the length of the axis—that is to say, in hypermetropic eyes. For, if simple traction on the choroid could produce the cone, it would make no difference how short the axis was; all that would be necessary would be an increased action of the muscle, and this we get in hypermetropia. Now, not only clinical experience, but actual statistics, show, as has already been pointed out, that the crescent is found less frequently in hypermetropic eyes than any other. Moreover, if traction on the choroid could and did produce the cone, we should expect to find it in all eyes, no matter what their refraction, at the *inside* of the nerve, since this would be the place of all others in the circumference of the nerve where the traction would be soonest and most powerfully felt, for the simple reason that it is the shortest line between the two points of attachment. Moreover, the crescent would have a rapid tendency to become circular. But ninety-nine times out of a hundred the cone is at the outside of the nerve, and there remains.

But not only do we have positive proof in hypermetropic eyes that increased action of the ciliary muscle, *per se*, does not produce the cone,

but we have equally strong *negative* proof, in myopic eyes; for the greater the myopia, the less the positive contraction of the ciliary muscle. And many cases occur of the development of the cone towards adult life in eyes which were not at the time of development of the crescent using, nor had ever used, any active accommodation at all; that is, in eyes whose far point had always been from twelve to eight inches. Of all eyes these are the most prone, on over-use, to progressive myopia and the formation of the cone, while it is a clinical fact that, in many of these cases of rapidly increasing myopia, the myopia is at once checked by carrying out the far point by glasses which decrease the amount of convergence, but which increase sometimes to a great degree the demands on the muscle, especially where, as in young people, we completely neutralize the error in refraction. I do not mean to say that the cone is not due to irritation and traction, for I am firmly convinced that traction on the choroid in the plane of its extent, and pressure on its surface, are the principal if not the only causes of the cone. But what I do mean is that this traction takes place from extension at the posterior pole of the eye, not by the contraction of the ciliary muscle at the anterior parts.

It has never been demonstrated in the slightest degree that the ciliary muscle exerts the least traction on the posterior parts of the choroid. Indeed, the little experimental evidence which we have is directly opposed to such a supposition, as is indeed all the clinical evidence. There is, moreover, to say the least, a strong doubt whether the muscle exerts any traction even on the anterior portions of the choroid, and some of those who have been hitherto the most enthusiastic supporters of the theory of the meridional portion of the muscle being a direct "tensor choroideæ," seem to have modified, if not completely changed, their views. Thus Iwanoff (42) latterly, after describing the anatomy of the meridional portion, and its mode of insertion into the *L. suprachoroidea*, says: "Now, with such a disposition of the meridional portion of the muscle with the *L. suprachoroïdea*, and with such a structure of this latter, it is self-evident that the deep layers of the choroid (choriocapillaris and middle choroid) cannot be essentially stretched. Consequently, the entire effect of the contraction of the ciliary muscle will limit itself to an extension of the ciliary body, which, as is known, is in the closest connection with the zonula of Zinn, while in the choroid itself, at the most, there will be only an extension of the L. suprachoroidea. This is perfectly evident when we bear in mind that that part of the choroid which is situated behind the *ora serrata* has no direct connection whatever with the zonula." Nevertheless, that enforced and maintained contraction of the ciliary muscle should produce that nervous exhaustion and irritation, with altered nutrition, which always occurs in the case of an overtasked muscle, is most natural. That this irritation should extend to the surrounding parts, causing increased vascularity, and, what is more, increased secretion, by which the intraocular pressure is augmented, might, I think, occur to some degree, in spite, too, of the assertion of Leber that the vascular supply to the ciliary muscle is so arranged that the circulation is not impeded by its contraction. Still, from what has already been stated, I am inclined to believe that this increased intraocular pressure, which is so potent a factor in the production of myopia, occurs much more frequently from other causes, especially from faulty convergence, than from the simple action of the ciliary muscle. This leads me to believe, although I appreciate most highly the labors of

Dobrowolsky,[1] that spasm of the ciliary muscle, so well recognized and described by the elder writers, has been somewhat exaggerated by the younger school both as to its frequency and the amount of influence it exerts in the production of myopia.

I have not the time to go into an extended discussion of this question, which it surely deserves, and must therefore content myself by pointing out the fact that it would appear that two important conditions have been ignored in the works of Dobrowolsky and his followers, Schiess-Gemuseus(43) and Dr. Derby(44) of Boston. The first is the physiological effect of atropine, which is to reduce the refraction to an amount which, according to Donders(45), would be expressed by $+\frac{1}{60}$, or even $+\frac{1}{40}$. The ordinary emmetropic eye then under atropine would be a hypermetropic eye of $\frac{1}{60}$. Are we to assume, then, as Dobrowolsky does, that a decrease of refraction which amounts to only $\frac{1}{360}$, $\frac{1}{240}$, $\frac{1}{120}$, or even $\frac{1}{96}$, is the result of spasm, and not the action of the drug, when the physiological action is often equal to six times the amount; and especially are we to assume this when solid atropine has been used three or four times a day for three or four weeks, or even months?

Dobrowolsky(46) gives a table of 105 cases of myopia. In 69 of these there was a decrease after the use of atropine—that is, in seventy per cent. But of these cases, when we make an allowance for the physiological effect, only thirty remain. Of these thirty, after this allowance, six show a decrease of $\frac{1}{240}$ or less, twelve of $\frac{1}{120}$ or less, seven of $\frac{1}{60}$, three of $\frac{1}{40}$, and two of $\frac{1}{15}$ or less. So that there are only five cases in the entire number which show a moderate degree of spasm, and only two of these a high degree; and in all these five cases the myopia is of an excessive grade, varying between $\frac{1}{3.3}$ and $\frac{1}{2.2}$. Now, these high degrees of myopia are just the conditions in which we always expect, whether there be any insufficiency or not, an apparent increase in the refraction, caused by an excessive muscular strain at convergence. This is invariably accompanied with a displacement of the relative accommodation inward, and the slight temporary decrease in the refraction caused by the use of strong atropine invariably returns as soon as the atropine is left off, unless the strain on the convergence is relieved by suitable means. Exceedingly interesting in this connection are some of the results published by the earlier writers—Bonnet, Cuvier, Philips, and Jules Guérin—but particularly the case related by Giraud Teulon(47), of extreme myopia, in which tenotomy of the external rectus suddenly diminished the myopia by $\frac{1}{13}$, or from $\frac{1}{5}$ to $\frac{1}{8}$. Had this amount of decrease in refraction been brought to light by the use of atropine, it would certainly have been put down by these observers as due to spasm; and it just as certainly would have returned the moment the atropine had been discontinued, unless the strain on the interni had been removed. The analogue of this, the sudden development of manifest H, which had been previously latent, after tenotomy, is too common an occurrence to need any comment whatever. It strikes me, therefore, that want of attention to these two points, namely, the physiological action of atropine and the associated action of the recti interni on the accommodation, has led these observers into a false estimate of the frequency of spasm, and its predominating influence in the production of myopia. Certainly my own

[1] I cannot agree with a recent writer, who says: "To Professor Schiess belongs the credit of utilizing the researches of Dobrowolsky for ophthalmic practice." Whatever there is of merit in this matter belongs, both theoretically and practically, entirely to Dobrowolsky.

experience does not coincide with that of these observers, and I fail to find a frequent or great diminution, even in myopic eyes of young children, after the use of atropine. This I was glad to see had been the experience of Donders(48), as expressed by him at the last International Congress.

Up to this point we have been occupied with a consideration of the action of the ciliary muscle as a whole, but a theory has been started that contraction of the muscle can take place in the direction of one meridian alone, or in different meridians in different degrees at the same time. Thus, according to Dobrowolsky(49), a complete interchange of kind and degree of astigmatism, as well as change of direction in the axis, may result from these meridional contractions, so that an eye which was originally hypermetropic in one meridian may by a counterbalancing contraction of the muscle become an emmetropic eye, or an emmetropic eye an astigmatic eye, with M in one meridian alone, or M in all meridians, and more pronounced in one than the rest; and so on with a change in all the varieties of astigmatism which could be produced through positive accommodation. It is claimed that this is a fertile source of myopia.

That a slight change in a meridian, whether of refraction or direction, should take place, would not appear strange; for there is nothing absolutely stable in the human body. This would, moreover, be in accordance with what has been supposed possible by many and corroborated in some degree by certain investigations made by Woinow(50). But any such remarkable changes as are pointed out by Dobrowolsky, either in kind or degree, I have never met with myself, nor do I know of any sufficient corroboration of them by others. For this reason I do not feel warranted in expressing an opinion in regard to them; certainly not one which would imply a belief as to their active agency in producing myopia.

These views of Dobrowolsky were followed by those of Dr. Thomson(51), of Philadelphia, based on the old theory of the antagonistic action of the two portions of the ciliary muscle. According to these views, not positive accommodation alone, as with Dobrowolsky, but even negative accommodation took an active part, through the contraction of the radial fibres of the ciliary muscle as opposed to the circular fibres. Thus a defined traction in a meridional direction was brought to bear on the choroid, which would naturally exert its influence at a corresponding point at its attachment at the circumference of the disk. This would produce the cone, which would then lie in the plane and direction of this traction.

I can only say in regard to this that our present knowledge of the action of the ciliary muscle does not support this conclusion. For notwithstanding the many attempts to prove the fact of negative accommodation, ever since the discovery of the ciliary muscle, not the slightest trace of its existence has ever been demonstrated; while on the other hand the fact of its non-existence has been, it would seem to me, incontestably shown. Until, then, the existence of negative accommodation has been proved, it would be a waste of time to speculate on what would be its effect on myopia, or rather what its effect is. We have no right to assume both the cause and effect too. But admitting the existence of negative accommodation to the fullest degree, even to the extent that it surpasses the positive, many facts would have to be explained before its effect on the cone could be admitted. First, why is it that we see the

highest degrees of myopia with immense cones, and either not a trace of astigmatism, or, if present, of such a very low degree as to preclude the idea that the cone is the result of the astigmatism? Secondly, why is it that we see such very high degrees of simple myopic astigmatism without a vestige of a cone? Thus in the past few months I have seen the following cases where there was no trace of a crescent: one case of $\frac{1}{5}$ c., two of $\frac{1}{6}$ c., one of $\frac{1}{7}$ c., two of $\frac{1}{8}$ c., one of $\frac{1}{10}$ c., three of $\frac{1}{11}$ c., and four of $\frac{1}{12}$ c.; all simple, myopic astigmatism. Thomson(52) himself has reported some cases of excessive asymmetry of the cornea, in which, to use his own words, "it is worthy of remark that in this last case, with such high degree of myopia and the use for years of glasses so unsuited, there was not the slightest appearance of the crescent at the optic disk." Again, it would have to be shown why it is that the cone sometimes runs in the same direction as the meridian of greatest curvature, and sometimes in that of the least, or again in neither. Then, too, if traction in one meridian had anything to do with the direction of the cone, why is it that it is limited so often to the outside of the nerve, and does not extend equally in the same direction on the opposite side? since it can hardly be assumed that these meridional contractions take place only in one-half of the ciliary muscle, and this, in the vast majority of the cases, the outer half.

We should have also to explain why it is that in sections of myopic eyes we find the choroidal pigment layer drawn away from the outer edge of the nerve and *over* the inner edge. In regard to the appearances of traction upon the vessels, and other details of the fundus as seen with the ophthalmoscope in astigmatism, I would say that this, as far as my experience goes, corresponds to the distortion produced by the optical defect of the refracting media, which causes the line of traction to appear to be always in the meridian of greatest curvature.

This brings me to the close of my remarks, from which I would in keeping with the condensed character of my paper make the following brief conclusions:—

I. From the fact that there is so large a percentage of children who are myopic, but whose parents are not near-sighted, while the myopia increases directly with the amount of increased tension of the eyes, and from the fact that an interchange of refraction may occur, whereby an eye which is not congenitally myopic may become so in spite of hereditary tendency, it would seem to follow that hereditary predisposition, though undoubtedly a potent cause, is not only not the sole cause, but is not even the predominating cause of myopia.

II. In regard to the second question, as to whether the ciliary muscle acting through faulty refraction can produce myopia and the cone, I conclude that the action of the ciliary muscle, taken by itself, exerts but little influence on the production of myopia, and still less on the formation of the cone.

I cannot refrain before closing from asking you once more to bear in mind that the questions submitted were not as to what the causes of myopia were, but simply the influence of two fixed and defined factors in its production. The briefest consideration of these two subjects which I could possibly make, has already led me beyond the limits of the time allowed, and I fear also of your patience. I have for these reasons been compelled to forego saying much which I am conscious that a just consideration of the subject would demand, and to discard much that I had already written.

Discussion on Dr. Loring's Paper.

After the reading of the preceding paper, Dr. J. Green, of St. Louis, said:—As bearing on the question of the influence of hereditary transmission, we must remember that we scarcely ever see myopic children whose parents and grandparents have been equally subjected to the general exciting causes of myopia. Taking, therefore, into account this absence of exciting causes in the case of the ancestors, it will not do to assume the absence of hereditary predisposition to myopia even where there has been no declared myopia in parents and grandparents. Again, in all our published statistics there is great imperfection as regards the recognition of astigmatism, and yet among the causes which produce indistinctness of vision, and thus favor the development of myopia, astigmatism certainly holds an important place. The statistics are thus of less value than many suppose, in clearing up this part of the subject. It is a very significant fact that in such cases of myopia as give the patient trouble enough to lead him to consult an oculist, we find astigmatism oftener present than absent; hence, in investigating the causes of myopia, we must make more careful studies of the refraction, not merely with reference to myopia and hypermetropia, but also with reference to astigmatism.

Dr. W. Thomson, of Philadelphia, said:—I think that Dr. Green has called attention to an important fact in alluding to the large number of cases of astigmatism which complicate myopia. That myopia is very often progressive, we know, but I think from observation that cases of myopia, pure and simple, are hard to find. High grades of myopia are, as a rule, characterized by astigmatism, and therefore we ought to consider whether most cases of propressive myopia have not commenced as slight cases of astigmatism. If we accept the conclusions of the paper, the question of progressive myopia would be hopeless, and we would have nothing to do but to look on and see people growing worse day by day. If it is conceded that astigmatism is often an efficient cause of myopia, we have then a remedy in cylindrical glasses. I think that astigmatism is one of the active causes of progressive myopia.

Dr. Loring said:—I would call attention to the fact that astigmatism was not mentioned in the question for discussion, but I admit that it has something to do with myopia. Dr. Thomson takes a gloomy view of the subject. I believe that, if we go on as in Germany, the time will come when myopic refraction will predominate. In keeping children in school twelve hours a day, poring over books, a great hygienic principle is overlooked, and, as long as

this is done, so long will there be myopia. I cannot agree that the time will ever come when myopia will be prevented by the use of cylindrical glasses.

Dr. H. W. Williams, of Boston, said:—Dr. Loring says justly that myopic astigmatism is a form of myopia. I think it is conceded that hypermetropia and astigmatism are hereditary. I know several instances in which persons are myopic in one eye, and emmetropic or hypermetropic in the other, and I would ask if there is a hereditary predisposition to myopia in one eye, and not in the other? And I have seen such cases, in which at a later period the myopia has increased, and in which the hypermetropic or emmetropic eye has become myopic. I am satisfied that myopia is largely due to artificial causes.

The President, Mr. R. Brudenell Carter, of London, said:—I remember the case of a young lady who was brought to me with a low degree of hypermetropia in one eye, and a high degree in the other. In the case of her father and mother both eyes were hypermetropic. I do not believe that statistics will enable us to arrive with certainty at any conclusion upon this subject. In looking back I can recall a few cases of myopia which were the result of accident. I remember at least one case in which this condition was produced by a blow.

Dr. Thomson said:—With regard to Dr. Loring's second conclusion, I think that the whole question resolves itself into whether or not the ciliary muscle is a single or a double muscle, and that unless new light is thrown on the subject by an appeal to clinical observation, there is nothing to do but to accept this conclusion. I am convinced that the changes in the back part of the eye in myopia have something to do with the existence of astigmatism, and that the appearances which they assume are largely dependent upon the direction of the principal meridians of the astigmatic eye. If a conus is found in any part, there will be found to be a relation between the direction of the conus and that of the cylindrical glass which gives the highest vision. I believe that I have established the fact that in many cases of myopia of high grade, say one-fifth, one-sixth, or one-seventh, in which neutralizing spherical glasses have been habitually worn, the optic nerve is free from distortion, and has no displacement, but that when astigmatism, even of low grade, is found conjoined with a high degree of myopia, a conspicuous conus will be found.

Dr. E. Williams, of Cincinnati, said:—I have seen several cases which I may cite in confirmation of Dr. Thomson's remarks. I remember the cases of a distinguished lawyer and of a merchant, both over fifty years of age, who had worn glasses since they had left school, and in neither of them was conus found. When we find a patient wearing the proper glasses, and seeing perfectly with them, we rarely find a conus, but when vision, even with the glasses, is more or less indistinct, we may expect to find the conus.

Dr. S. D. Risley, of Philadelphia, said:—I think that we rarely see progressive myopia with conus without astigmatism, and, on the other hand, that conus is not confined to myopic eyes, but is a very frequent occurrence in hypermetropic eyes with astigmatism. I recall two cases in which conus and myopia had appeared while under observation, and were attended by marked asthenopia which was relieved, and further choroidal change arrested, by the rest afforded the ciliary muscle by a carefully adjusted, correcting glass. I am convinced, from clinical experience, that the ciliary muscle has much to do with progressive myopia and the formation of the conus.

Dr. Thomson said:—I know of a number of cases of asthenopia from insufficiency of the internal recti, which bear upon this question. In one case, in which the asthenopia had existed over a period of thirty years, and had caused much distress, and in which the asthenopia was perfectly relieved by the use of proper prismatic glasses, there was absolutely no trace of conus in either eye.

Dr. Loring said:—The use of concave glasses often stops the development of the conus and the myopia, and, nevertheless, the use of the glasses forces the accommodation more than when they are not employed. All admit that concave glasses are useful in myopia, yet concave glasses act directly upon the ciliary muscle. That the ciliary muscle has two antagonistic functions is, to say the least, extremely improbable.

ON THE RELATIONS BETWEEN CORNEAL DISEASES AND REFRACTIVE LESIONS OF THE EYE.

9

BY

GEORGE T. STEVENS, M.D.,

OF ALBANY, N. Y.

Of the various structures of the human body, few have been subjected to such thorough, critical, and we may add profitable, examinations in respect to the histology and pathology of their tissues, as has the cornea. The names of many of the most learned and illustrious investigators are inseparably connected with this small structure, and the extent and value of their researches indicate its importance. Yet it must be conceded that of the advantages derived from the histological and pathological studies of this part, comparatively few have reverted to the structure itself, and candid observers must agree that in the etiology of corneal diseases the advance has not been in proportion to the added knowledge of its structure and pathology.

A review of the history of the etiology of corneal diseases would show that, since writers of half a century ago, after allowing for the agency of mechanical and chemical injuries and the pressure incident to certain forms of conjunctival disease, united in ascribing the cause of corneitis to scrofula and arthritis, few important advances have been made in determining the causation of these diseases. To the genius of Mr. Hutchinson we owe the discovery that in a clearly defined class of cases of corneal disease, the cause may be found in the diathesis peculiar to inherited syphilis, and that if we would best meet the indications for treatment in these cases we must directly attack the inherited taint. But the proportion of such cases is not large, and there remain after excluding those which arise from mechanical pressure, injuries, chemical irritations, and a few other exceptional causes, the very large residuum of cases which by nearly all authors are regarded as manifestations of struma.

Of phlyctenulæ of the cornea, the form of corneal disease which the surgeon most frequently encounters, a learned French writer of recent times[1] says that the pustules are the first and the most frequent manifestation of scrofula; they are, he says, benign scrofulous exudations. Although this view is not fully accepted by some modern writers, it meets with but the mildest opposition, and the doctrine that the prevailing cause of corneal diseases and especially of phlyctenulæ is struma, is, I believe, the one generally accepted. The truth is that the condition called struma is far more frequently developed by corneal diseases than are corneal troubles developed by struma. One of the most positive evidences of the existence of struma, is supposed to be found in the presence of enlarged cervical glands, but the enlargement of these glands does not usually precede the corneal disease, but is its result.

The fact, well known to ophthalmic surgeons, that patients who have been cured of corneal diseases are quite liable to return after a few months,

[1] Bazin, Leçons sur la Scrofule.

or even weeks, with renewed attacks of the disease, showing conclusively an inherent tendency to such troubles, led me a year ago to seek for the cause of the tendency. The excessive nervous irritability, photophobia, and muscular spasm, and the general failure of nutrition in these cases, induced me to regard corneal diseases, especially of the phyctenular form, as a manifestation of functional nervous derangement. The fact of the easy cure and the frequent recurrence of the diseases strengthened this opinion, and as I had at that time been led to the belief that many functional nervous diseases owed their origin to anomalous refraction of the eyes, I turned to the eyes themselves to seek for the cause of irritation. A few careful examinations satisfied me that a more extended search should be made in this direction, but the difficulties encountered in ascertaining the refractive condition of the eyes of patients suffering from corneitis, especially from phlyctenular corneitis, are great; the intolerance of light, the youth of the patients (for phlyctenular corneal troubles are most frequently found in children from two to eight years of age), and their general irritability, all contribute to render such examinations tedious to both patient and surgeon. To these difficulties I attribute the fact that the well-known maxim among ophthalmic surgeons, to test the refraction of all diseased eyes, has been so far disregarded; for the practitioner whose time is fully occupied by the usual duties of his profession, will find the attempt to examine a large number of these patients in this respect a severe tax upon his time and strength.

I cannot better illustrate the result of my search in this direction than by relating the history of the following case. The first part of the history well illustrates the oft-repeated experience of every ophthalmic surgeon, while the second part will illustrate my own experience in several cases since my attention has been specially directed to this subject.

L. R., a bright boy seven years of age, was, about two years ago, brought to me, suffering from phlyctenular ulcers of both eyes. He had, previous to the eye trouble, enjoyed excellent health, had passed through the usual experienee of childhood in respect to infantile diseases with safety and ease, and was regarded as a perfectly healthy and robust child. There was no history of syphilis or of scrofula in the family of either father or mother, both of whom were perfectly healthy people. Treatment for a few days by means of atropine and stimulants applied to the mucous surfaee of the eyelids, sufficed to effect a speedy cure of the ulcers, and the boy remained well for about three months, when he passed through a similar experienee which was repeated a third and a fourth time within a little more than a year. At the close of the seeond attack, I observed that the cervical glands were swollen as they had not been previously, and with each attaek there was more general irritability and more evidence of defective nutrition. During an attaek about a year sinee, his mother called my attention to a defeet in her own eyes, which, on examination, I found to consist in hypermetropie astigmatism of $\frac{1}{30}$, and whieh indueed me to test the refraction of the boy's eyes. I found hypermetropia $\frac{1}{30}$, without astigmatism, and advised that he be required to wear + 42 glasses when engaged in studies or in playing with toys. My advice was accepted, and the boy's eyes have sinee remained well, and with the correetion of the refractive evil the so-ealled strumous symptoms disappeared.

The following case, which has been reported in another connection, will illustrate the relations existing between this and another form of manifestation of nervous trouble.

Mr. F. A. R., of Minnesota, consulted me in September last in regard to his little daughter's eyes. She was a bright girl of ten years, with a defect in her

speech, and was evidently suffering from chorea. On account of her nervous condition she had been kept out of school for more than a year. The trouble for which I was consulted was the presence of a number of small ulcers at the border of the cornea. On testing the refraction, I found astigmatism requiring for its correction a + 36 cylinder. Glasses were procured, and after brief treatment for the ulcers, resulting in their cure, the father returned with his child to his western home. In the latter part of March, of this year, he again presented the child for treatment, she being again subject to corneal ulcers. I learned that from the time of leaving Albany the child's health had greatly improved, and her nervous symptoms had disappeared. A month or two previous to the last visit, however, her glasses were broken, and she was without them for some time. The nervous symptoms began to return, and the corneæ were again affected with ulcers.

In looking over the records of one hundred and fifty cases of corneal disease in which the refraction has been examined with as much accuracy as the difficulties necessarily encountered would permit, I find that in 80 per cent. there have been serious refractive lesions. Even in two cases which were typical of the physical conformation so clearly described by Mr. Hutchinson as characterizing the offspring of syphilitic parents, a high degree of hypermetropia was found after the infiltrated corneæ had become sufficiently transparent to allow of a determination of the refractive condition, and it is interesting to remember that the flattened facial features described by Mr. Hutchinson are those recognized by ophthalmologists, and so well described by Prof. Donders, as indicative of hypermetropia. In these cases, as in all others in which the refraction has been determined, after the cornea has been affected, allowance must of course be made for changes in the form of the cornea which may have resulted from disease, but as in each of the cases alluded to a high degree of hypermetropia was found ($\frac{1}{18}$ and $\frac{1}{14}$) the defect could hardly be ascribed to this cause.

In my efforts to determine the refraction in these cases, I have often been obliged to be satisfied with an examination of the unaffected eye by means of test letters, or by the ophthalmoscope alone. In several instances the examinations have been made after recovery from the disease. Among the refractive errors, hypermetropia seems to rank first as a cause of corneal affections; second, astigmatism; and third, unequal degrees of myopia. A larger number of cases than I have examined would be necessary to determine the relative frequency of these conditions. Simple myopia of equal degrees in the two eyes, I have not found except in young children in whose cases the refraction has been determined by the ophthalmoscope. In these cases, I suspect an astigmatism not recognized by this means of examination.

It is important to notice two conditions which are often associated with corneal diseases: First, the herpetic eruption which is so common in phlyctenular corneitis; and second, an inflamed condition of the free border of the eyelid. The herpetic eruption which appears about the lips, cheeks, and nose, in cases of phlyctenular corneal troubles, is conceded to be the result of irritation of branches of the fifth nerve. That it is due to the reflex irritation from the ciliary nerves, I think it reasonable to suppose, for I have often seen these herpetic eruptions about the cheeks, nose, and lips, disappear quickly after correcting the refraction of the eye, and with no further treatment. The blepharitis would also in most instances seem to be one of the manifestations of reflex irritation from the same cause, as I have long observed; and the

swelling of the lids, which is of itself sometimes the immediate cause of corneal lesions, is, I believe, one of the various results of the peripheric irritation beginning in the ciliary body.

That a reflex nervous irritation, like that arising from the strain upon the ciliary muscle in erroneous refraction, can interfere in the nutrition of the cornea, there can be no doubt; and, if we watch the course of a corneal phlyctenula, we shall see that nutrition is disturbed first by irritation of the vaso-motor nerves of the conjunctiva; for here we observe, before the appearance of any efflorescence of the cornea can be discovered, the fasciculus of red vessels, and indeed, if promptly met by appropriate treatment, this can usually be made to disappear before the herpetic pustule is developed at all.

May it not be a mistake to regard the herpetic pustule as the centre of irritation around which the vascular injection of the conjunctiva forms an objective expression? Were this the case, would not the pustule appear first, whereas, frequently, it is entirely aborted? Is it not more probable that the condition of the vessels in this congested fasciculus, is such as to clog the passages through which nutritive material should pass to supply certain portions of the cornea, and that the portion in which nutrition is most defective, suffers first from this interference?

SECTION ON OTOLOGY.

PRESIDENT OF THE SECTION.
CLARENCE J. BLAKE, M.D.,
OF BOSTON.

VICE-PRESIDENT.
ALBERT H. BUCK, M.D.,
OF NEW YORK.

SECRETARY.
H. N. SPENCER, M.D.,
OF ST. LOUIS.

THE IMPORTANCE OF TREATMENT OF AURAL DISEASES IN THEIR EARLY STAGES, ESPECIALLY WHEN ARISING FROM THE EXANTHEMATA.

BY

ALBERT H. BUCK, M.D.,
OF NEW YORK.

The object of selecting the subject of this paper for discussion by a body of men interested in otology, must be, not to draw out the different opinions of otologists on the subject (for there can certainly be but one opinion), but to have the attention of the profession at large directed to the importance of early treatment in aural diseases. The pleading of a single individual would perhaps fail to carry conviction to the minds of many members of the profession, while the same statements, made by the same individual acting as the mouth-piece of such a body of skilled men as is here gathered together, may be likely to receive the thoughtful consideration which the subject demands.

In discussing this subject, I shall take into consideration chiefly the acute, purulent affections of the middle ear, as it is in these that judicious treatment proves so beneficial, and the want of it at times so disastrous. In catarrhal affections it might also be shown that treatment in the early stages of the trouble was in general productive of very satisfactory and marked results, while in the later stages it rarely proved of any benefit whatever. It will be sufficient, however, for my present purpose, to make use only of those acute affections of the middle ear which naturally end in the formation of pus, and which very often become chronic.

The question of the frequency of chronic otorrhœa, is a difficult one to determine with any degree of accuracy. Owing in part to the prevailing popular belief that it is dangerous to arrest a discharge from the ear, and in part to the answer which very many physicians give to the parents of

such patients—" your child will outgrow it"—hundreds upon hundreds of individuals never present themselves for treatment either in private (aural) practice or in the clinics of our public institutions. Hence we have no means of finding out accurately how large a percentage of the population of any given community is afflicted with this morbid condition. We know, however, that these cases constitute from twenty to thirty per cent. of all cases of ear disease that come under the aurist's care, either in hospital or in private practice. We also know that among our acquaintances a certain number are troubled, and have been perhaps for years, with a discharge from one or both ears. Again, if we inquire how the disease originated, we find that, in a large proportion of the cases, it is referred back to an attack of scarlet fever, or measles, or nasal catarrh. In this way we get hold of two important facts: first, that chronic discharge from the ear is a common disease; and, second, that taking cold, and the exanthematous diseases, are the chief sources from which it originates. Two questions here present themselves: (1) Is a chronic discharge from the ear a sufficiently serious affection for either the physician or the patient to give much thought to it? and (2), admitting the serious nature of the disease, can anything be done to diminish the prevalence of such chronic otorrhœas?

Satisfactory answers to these two questions will furnish the best elucidation of the title which stands at the head of this paper.

I. *Is Chronic Discharge from the Ear a serious Affection?*—I answer unhesitatingly, yes. In the first place, it is annoying to the patient and disgusting to those who associate with him. In the next place, it is an indication of the existence of a process which may at any time seriously threaten the patient's life. Here, again, statistical proof of the correctness of my statement is not easy to furnish. Medical literature contains numerous accounts of cases of chronic otorrhœa that have terminated fatally. Almost every practitioner, too, has met with one or even several such cases in the course of his practice. Many also have seen such cases terminate fatally under the form of meningitis, and have never once thought of the part played in the disease by the chronic otorrhœa. These are well-known facts, and admitted, I think, by all. But how does an inflammation of the ear pass into the condition of a chronic otorrhœa, and how may the latter cause the death of the patient? To render this clear, let me narrate to you the probable history of such a case.

A strong, healthy boy, ten years old, is taken ill with scarlet fever. The disease runs a moderately severe course, and bids fair to subside without any serious after-effects. The tonsils are red and swollen, and the entire naso-pharyngeal region is evidently in a markedly inflamed condition. While in this state—say in the second or third week of the disease—the boy begins to complain of an earache. The first night, warmth is applied to the ear, and in this way the boy gets some temporary relief. The next day, however, the pain continues, and the family physician, who perhaps by this time has discontinued his daily visits, is consulted as to what shall be done to relieve the boy of his earache. Laudanum is prescribed; a drop or two of it to be instilled into the ear, and a piece of cotton-wool saturated with the remedy to be inserted into the outer canal. This too, perhaps deadens the pain a little, but still the boy passes a second night in suffering, and the third day finds him steadily growing worse. By this time the earache proper has become merged in a painful and throbbing sensation, involving not only the ear itself, but

also the entire side of the head, and especially the mastoid and occipital regions. The instillation of laudanum is repeated, and perhaps sweet oil is added. The third night is passed in miserable suffering, the boy obtaining a few snatches of sleep by the aid of opium administered internally. On the fourth day—a large blister in the mean time having been applied behind the ear, only to add to the boy's discomfort—a slight discharge makes its appearance at the outer orifice. As this discharge becomes more copious, the pain subsides, and in the course of a few days the patient finds himself able again to eat, sleep, and move about as when he was well. For a year or more afterwards he remains free from serious pain in the ear; the discharge, however, persists, and at times there is a sense of discomfort in the ear, perhaps not amounting to actual pain, but still sufficient to indicate the existence of a tolerably active inflammatory process. Finally, the patient some day contracts a bad "cold;" the otorrhœa ceases, the pain in the ear and corresponding side of the head becomes intense, the parts behind the ear become very painful and tender, there is fever—in a word, the inflammation of the tympanum has spread to the adjacent bony structures and to the meninges of the brain, and death soon follows. Death may also follow in other ways, but for our present purpose it is not necessary to describe other modes of fatal termination.

Now, to appreciate clearly how dangerous a disease an inflammation of the middle ear may become, and to understand fully the *rationale* of a successful treatment, it is necessary that one should possess a tolerably clear idea of the anatomical relations of the middle ear. These are, in brief, the following:—

The middle ear (or tympanum) is a small cavity about five-eighths of an inch in length, half an inch in height, and from an eighth to a quarter of an inch in breadth. The drum-head, or membrana tympani, constitutes the greater part of one of the sides of this cavity—the outer one—but at all other points (with some unimportant exceptions) its walls are of bone, covered by an exceedingly thin, vascular mucous membrane. In health, this cavity possesses an outlet (the Eustachian tube), but when its lining mucous membrane becomes inflamed, this outlet undoubtedly closes, and we then have to deal with an inflammation occurring in a closed cavity, the walls of which are everywhere of bone, except at one spot, and here the resistance of a strong fibrous membrane must first be overcome before the fluid can escape, and before the conditions of a closed cavity can be done away with.

Now let us suppose that inflammation has attacked this cavity. What takes place? The vessels of the mucous membrane become gorged with blood, the mucous membrane itself becomes swollen and œdematous, and the valve-like tympanic orifice of the Eustachian tube becomes closed to all secretions that might otherwise find an escape through this channel. This is the *first stage* of the trouble, and it may last only a few hours, or it may be prolonged for even three or four days. This is the stage in which the application of a few leeches in the neighborhood of the ear may suffice to check the entire trouble. But, if the inflammation continue, stasis will occur in the capillaries and veins, and serum will be forced by arterial (cardiac) pressure through the walls of the bloodvessels, through the surrounding tissues, and finally into the cavity of the tympanum. After the cavity has become filled with the exudation, each succeeding portion of fluid exuded must find room for itself by forcing the membrana tympani outwards. The disease has now reached its *second*

stage. The tympanum is filled with serum, in which pus corpuscles are rapidly increasing in number, the membrana tympani is bulged outwards and pulsates, capillary and venous stasis is general, and great pressure is being exerted upon all the soft parts contained not only within the tympanum proper, but also within the communicating system of bony cavities, the antrum and mastoid cells. If now the membrana tympani be not abnormally resistant, the pressure will soon cause a thinning, and eventually a rupture, of the membrane at some particular spot. The pressure, which is the chief source of the pain, then ceases, the exuded fluid becomes more decidedly purulent in character, and escapes through the perforation, and the parts in due time return to a natural condition. In a large minority of cases, however, the termination is not so favorable. Owing probably to the great resisting power of the membrana tympani, the intra-tympanic pressure continues for a much longer period—perhaps even for several days—before a perforation is finally established. In these cases, it must be remembered that the tympanic mucous membrane is also functionally a periosteum. Hence the continued pressure is apt to result in superficial death of the underlying bone in one or more places. But there are also other points that should be remembered: the bloodvessels of the tympanic mucous membrane communicate freely with those of the adjacent dura mater, which is separated from the mucous membrane by only a thin septum of bone, and the mastoid veins empty directly into the lateral sinus.

If all these points be borne in mind—the anatomical and pathological conditions, and the impotent or even harmful treatment pursued—should any one be surprised at the terrible results that often follow inflammation of the ear, or wonder any longer at the large percentage of individuals in every community who go through life with an offensive discharge from this organ?

II. This brings us to our second question: *Can anything be done to diminish the prevalence of such Chronic Otorrhœas?*—In answering this question we shall confine ourselves, in accordance with the spirit of our subject, to the consideration of those measures which tend to prevent the inflammation from reaching what might be termed a *third stage*, one that is characterized by inflammation of neighboring organs, by proliferation of the soft tissues, and by carious processes in the subjacent bone. In a few cases, in the early part of the attack, warm applications and leeches are sufficient to prevent the inflammation from reaching the higher, second stage. In the majority of cases, however, we are unable to prevent this increase, and are consequently brought face to face with a middle ear in the condition of inflammation to which I have given the name of second stage. This is the time when paracentesis of the membrana tympani produces such beneficial effects, and the earlier it is performed, in this stage, the greater its efficacy. In this one slight operation, which in itself is neither dangerous nor very painful, lies the power to prevent the whole train of disagreeable and dangerous symptoms to which I have alluded so fully above. It is not far from the truth to say that every fatal case of purulent inflammation of the middle ear must, at some time in its course, have passed through a stage in which, by a resort to this operation, the progress of the disease might have been arrested, and the tendency of its course changed from an unfavorable to a favorable one.

In illustration of the speedy relief from pain which often follows the

operation, especially in children, let me narrate briefly the following case:—

A child, three years old, had been complaining of earache in the right ear during the greater part of the day. (For several days previous to this, she had been suffering from a marked nasal catarrh.) The pain in the ear was paroxysmal in character, and the child evidently had a high fever, though no measurement of the temperature was made with the thermometer. As night came on, the pain became more severe, and the intervals between the paroxysms shorter. Toward morning I was sent for, as the pain had become constant, and the child was in great suffering. An examination with the speculum and reflected light showed an œdematous and bulging membrana tympani (posterior half), the neighboring parts being very red, though as yet but little swollen. In the most prominent portion of the membrane I made an incision scarcely three millimetres in length, and involving simply the different layers of the membrana tympani. This was almost immediately followed by a watery discharge (without the aid of inflation), which ran down over the child's cheek. At the end of three or four minutes the child had ceased crying, and in less than a quarter of an hour she was fast asleep. At first the discharge was very abundant, and mainly watery in character, but it steadily diminished in quantity and became thicker, until finally on the fourth day it ceased altogether. On the tenth day the most careful examination of the ear could not detect any trace of either the inflammation or the artificial opening.

It would have served my purpose better, had I been able to offer in illustration a parallel case of acute, purulent inflammation following scarlet fever or measles; but unfortunately I cannot find in my records a single such case which came under observation as early as the second or third day after aural symptoms had manifested themselves. The morbid process, however, is practically the same in both cases, and the benefit to be obtained by early surgical interference cannot be materially less in cases following scarlet fever than in those following an acute nasal catarrh. The tendency to desquamation, and the enfeebled state of health following a moderately severe attack of scarlet fever, may, it is true, prolong the subsequent subacute stage of the aural inflammation for a few weeks, but the prospect of ultimate complete *restitutio ad integrum* is almost as certainly secured by timely interference in the one case as it is in the other. No harm can come from perforating the membrane too early, but months or even years of annoyance and suffering may be entailed upon the patient by resorting to the incision after the mischief has already been done. It then often fails to relieve even the pain.

In calling special attention to this operation, I do not wish to be understood as advocating it as the *only* means of treatment in such cases; I simply choose it because it is the *most important* one, and because its wonderful efficacy is susceptible of proof.

This is perhaps the best place to comment upon the view held by the late Mr. James Hinton, of London, respecting the efficacy of paracentesis of the membrana tympani in acute affections of the middle ear. In his work on "The Questions of Aural Surgery" (pp. 130 and 131), I find the following: "Since the real relief of the symptoms depends upon the escape of the matter through the membrane, it would seem an obvious inference that the membrane should be, at the earliest possible period, incised. And this is recommended by almost every writer; but experience of this method has left a doubt upon my mind. In the few cases in which I have had recourse to it during the acute stage of an inflammation, I have not found the results very satisfactory, and in two in-

stances in which the inflammation existed on both sides, and I incised one membrane only, the progress of recovery seemed retarded rather than expedited; I must, therefore, hold an undetermined position on this question." Such an opinion, coming from one whose authority in otological matters is so weighty, is calculated to prevent many from resorting to the operation, and that, too, notwithstanding the fact that in another part of the same work (p. 133) he says: "But whatever may be the best method of treatment in simple, acute catarrh[1] of the tympanum, there seems to be no doubt that immense evil might be prevented by free incisions of the membrane in very many of the cases in which it becomes inflamed during the course of the exanthemata." The example which Mr. Hinton cites, in evidence of the doubtful efficacy of paracentesis, furnishes at the same time a satisfactory explanation of the reasons why the incision failed to afford relief. In the first place, the incision consisted of a mere "prick with a cataract knife," and, in the second place, it was not made until the eighth day of the attack, or, in other words, late in what I have described as the second stage. Under such circumstances it is certainly not to be wondered at that the paracentesis failed to afford the desired relief.

My own experience leads me to recommend the operation *unhesitatingly;* in fact, without it, I believe the physician will be able to do comparatively little toward preventing those disastrous results to the hearing, to the general health, and even to life, of which I have already spoken more than once in this paper.

On looking over my records of cases (in hospital and private practice), I find that I have had occasion to perform this operation seventy-six times, on fifty-eight persons, for the relief of pain. In each of these cases the membrana tympani was either "red and swollen," or "bulged outwards," from the pressure of the fluid in the middle ear. In seven cases the paracentesis was performed on the 2d day of the disease, in four on the 3d day, in seven on the 4th day, in five on the 5th day, in four on the 6th day, in two on the 7th day, in ten on the 8th day, in two on the 10th day, in six between the 11th and 15th days, in one on the 20th day, in two between the 21st and 25th days, in one on the 30th day, in three between the 31st and 55th days, and in four at unknown periods. In twenty-nine cases, permanent relief from the pain was afforded within a few minutes or hours; in six other cases immediate relief was afforded, but the pain returned, either the next day or on some subsequent day; in eight others, the pain did not subside until the 2d, 3d, or 4th day after the incision; in four others, the operation afforded no appreciable relief; and finally, in eleven instances, the patients did not return to report the result of the operation.[2] Of the twenty-nine cases in which the operation proved quickly successful in relieving the pain, six had reached the 2d day of the disease, three the 3d, four the 4th, four the 5th, two the 6th, two the 7th, four the 8th, one each the 12th, 14th, and 15th days, and one an unknown stage of the disease. In other words, the operation

[1] Mr. Hinton's "simple, acute catarrh" is nothing more nor less than an acute inflammation of the middle ear, going on to the formation of pus, and to the exertion of a pressure equally great with that which takes place in the acute inflammation following the exanthemata. While, perhaps, the ultimate results are not quite as disastrous in the cases which develop in the course of a simple nasal catarrh as in those which accompany the exanthematous diseases, there is not a sufficient difference to justify any material difference in the course of treatment that should be pursued in the two classes of cases.

[2] These eleven cases all occurred in hospital practice.

may be said to have been quickly successful in cases chiefly of recent date. On the other hand, of the eighteen cases in which the pain returned, or in which there was little or no relief from the incision, five were subsequently relieved by incision of the mastoid integuments, eight by subsequent incision (or incisions) of the drum-head, and two by leeches. In twenty-five out of the fifty-eight cases, the day (of the disease) on which the discharge ceased was noted; in the remaining cases, either no note was made regarding this point, or the patients did not return to report their condition. In regard to the twenty-five, the facts are as follows: in six cases the discharge ceased on or before the 8th day of the disease, in seven between the 9th and 15th days, in two between the 16th and 22d days, in five between the 23d and 40th days, and in five between the 41st and 65th days. As far as the incomplete records go, therefore, in not a single case did there remain a permanent chronic otorrhœa with perforated membrana tympani.

Surely this record justifies me in recommending unhesitatingly the operation of paracentesis of the tympanic membrane. I am sorry to say that I have never had the opportunity of testing the value of this operation in those very cases in which we have every reason for believing that it would prove of the greatest value, namely, in those which occur in the course of the exanthematous diseases. Hinton, however, as we have seen, speaks in strong terms in its favor under these circumstances, and I believe that all or nearly all the authorities hold the same opinion.

Having shown how serious are the results which often follow an unchecked, or improperly treated, acute inflammation of the middle ear, and having also shown, as far as it is possible to demonstrate such a fact, that we are in possession of at least one means of preventing (in the great majority of cases, if not in all) these disastrous results, what more can I say to impress upon the profession "the importance of treatment of aural diseases in their early stages, especially when arising from the exanthemata?" The opinion expressed by Prof. Edward Clarke,[1] of Boston, in 1858, and reiterated by Von Tröltsch and Hinton—that a physician who treated a case of exanthematous fever without inquiring into the condition of the ear, was guilty of great neglect (or words to that effect)—might be uttered with as much appropriateness to-day. I would go still further, and say that a general practitioner who is unable to obtain a view of the external auditory canal and membrana tympani by means of the speculum and reflected light, is not properly fitted to practise medicine. While it may not be necessary for him to study otology, or to become skilled in aural manipulations, it is very necessary, if he wish to fulfil his duty toward his patient, that he should be able to determine by actual examination, whether or not the membrana tympani is being pushed forcibly outwards by the products of inflammation within the tympanum. If he be able to determine this point, and an hour's schooling will put him in possession of the necessary technical knowledge, I am sure that, where it is indicated, he will not be slow in taking successfully the second step, namely, the incision of the membrana tympani.

Medical students are taught very thoroughly how to amputate a leg, and their knowledge of the relations, distribution, etc., of arteries and nerves, will be found, at their examination for the degree of Doctor of Medicine, to be quite perfect; but has the new graduate the slightest

[1] American Journal of the Medical Sciences, 1858.

practical knowledge of how he should deal with an acute inflammation of the ear? Upon the medical schools, then, rests the chief responsibility for the prevailing indifference and ignorance among practitioners regarding these matters, and to the schools, therefore, the profession must look for assistance in bringing about a reform.

In conclusion, let me recapitulate briefly the main points which a consideration of the subject suggests:—

I. Chronic otorrhœa is at the present time a very common disease, due, in most cases, to the want of proper treatment during the acute stage of the affection.

II. It is by no means a harmless affection.

III. It may be fairly classed as a preventable disease, at least among those who possess a healthy constitution.

IV. Paracentesis of the membrana tympani, if resorted to during the first few days of the acute attack, and if not carried out too timidly, *i. e.*, if a free incision be made and not a mere prick, is almost a sure preventive of the subsequent, chronic disease.

V. The Profession at large, and especially the medical schools, should give this subject more earnest thought than they have in the past.

As some may be interested to ascertain further details regarding the cases referred to above, I append in a tabulated form the main points of interest in each of the fifty-eight cases, as far at least as my imperfect records furnish this information. And here I may say that it is not unfair to assume that the great majority of the patients in whom the result of the incision was not ascertained, failed to report their condition simply because they had been relieved of their sufferings, and did not feel the necessity of visiting the hospital again.

Tabular View of Fifty-eight Cases of Paracentesis of the Membrana Tympani.

No.	Age	Cause.	Condition of membrana tympani.	Condition of mastoid region.	Day of disease on which paracentesis was performed.	Relief from pain.	Day of disease (approx.) on which perf. healed and otorrhœa ceased.	Remarks.
1	17	Exposure.	Red and bulging.	Tender	7th	Speedy.	28th	
2	21	Not stated.	Bulging, but not very red.	Normal	2d	Immediate.	Not stated.	
3	32	"Cold in the head."	Œdematous and bulging; neighboring parts red.	Tender	6th	Entirely free from pain at end of 6 hours.	10th or 11th	Paracentesis repeated twice (with equal benefit) in same ear during following two years.
4	6	Not stated.	Posterior half bulging, red.	Not stated.	2d	Speedy.	Not stated.	
5	40	Sitting in a drau't of air.	Post. half red and bulging; small perf. in the ant. inf. quadrant.	Tender	14th	Relieved in 12 hours.	Not stated.	Three leeches also applied at same time.
6	40	Not stated.	Membrane bulging both anteriorly and posteriorly.	Not stated.	8th	Immediate.	Not stated.	Subsequent fresh attack. Incision repeated. Result not stated.
7	23	Not stated.	Red, bulging, and pulsating.	Tender	12th	Relieved in a few hours.	Not stated.	
8	25	Not stated.	Red and swollen.	Not stated.	11th	No marked relief till 4 days later.	26th	
9	32	Caught cold.	Post. half swollen and red; small perf. anteriorly.	Not stated.	8th	Pain gradually subsided.	Not statod.	
10	6	Not stated.	Red and swollen.	Not stated.	6th	Not known.	Not known.	Patient did not return to the Infirmary.
11	24	Caught cold.	Red and swollen.	Not stated.	About 21st	Not known.	Not known.	Patient did not return to the Infirmary.
12	33	Not stated.	Red and bulging.	Not stated.	3d	Pain gradually subsided; slight recurrence.	14th	Leeches also applied at the same time.
13	30	"Run over by a wagon."	"Much inflamed."	Not stated.	8th	Pain gradually subsided; no return.	Not stated.	
14	21	River bathing	Post. half red and bulging.	Not stated.	4th	Only temporary relief.	Not stated.	On the seventh day, two incisions in the membrana tympani, one anteriorly, one posteriorly; also leeches. On the thirty-seventh day opened a large abscess behind the ear.
15	14	River bathing	Post. half red and bulging.	Not stated.	5th	Pain soon subsided entirely.	Not stated.	
16	27	Not stated.	Red and bulging.	Tender	8th	Almost immediate relief.	Not stated.	
17	47	"Severe cold in the head."	Bulging.	Slightly tender.	End of 1st	Within two hours.	In the course of a few days.	Leeches also applied at the same time. Two days later the other ear became similarly inflamed, and at end of first day I incised membrana tympani in two places, affording escape, as in the case of the first ear, to bloody serum. Leeches also applied. Immediate relief followed.
18	8	Not stated.	Bulging.	Not stated.	2d	At the end of a few minutes.	7th	On the fourth day the other ear became painful. The following day incised the membrane and afforded immediate relief from pain, as in the case of the first ear.
19	49	Not stated.	Diffusely red background; landmarks not recognizable.	Very tender.	3d or 4th of decided pain; 21st of disease.	Very slight if any relief.	Not statod.	Relief obtained only by an incision of the mastoid integuments.
20	8	Not stated.	Membrane bulging.	Tender	Not stated.	Not known.	Not known.	Patient did not return to the Infirmary.
21	34	Not stated.	Bulging and red.	Not statod.	Not stated.	Not known.	Not known.	Patient did not return to the Infirmary.
22	28	"Took cold."	Œdematous, and bulging posteriorly.	Not stated.	Not stated.	Almost immediato relief.	Not stated.	

No.	Age	Cause.	Condition of membrana tympani.	Condition of mastoid region.	Day of disease on which paracentesis was performed.	Relief from pain.	Day of disease (approx.) on which perf. healed and otorrhea ceased.	Remarks.
23	17	River bathing	Red and bulging.	Not stated.	3d	Relieved soon.	18th	Two days later (fifth day) membrane again bulging and parts painful. Incision repeated. No return of pain afterward.
24	70	Not stated.	Posteriorly and superiorly, red and bulging.	Not stated.	About 42d	Pain mitigated, but not entirely relieved.	About 60th	Permanent relief not obtained until after incision of mastoid integuments on about the fifty-second day.
25	3	Not stated.	Post. half red and bulging.	Not stated.	7th	Relieved soon.	About 28th	
26	25	Syphilitic nasopharyngitis.	Membrane red and swollen; small perf. anteriorly.	Tender	About 8th	No material relief.	About 20th	Relief obtained permanently only by an incision of the mastoid integuments on about the fifteenth day.
27	29	Not stated.	Membrane red and swollen.	Tender	2d of acute exacerbation (about 53d since first attack).	Gradual subsidence with no return.	About 65th	
28	19	Not stated.	Membrane red and swollen.	Not stated.	4th	Gradual subsidence with no return.	39th	
29	57	Not stated.	Red and bulging.	Not stated.	10th	Immediate relief, but pain returned later, though not so violently	Not stated.	
30	22	River bathing	Posterior half bulging and red.	Not stated.	5th	Soon afterwards.	12th	
31	49	Not stated.	Post. half bulging and red; small perf. anteriorly.	Not stated.	5th or 6th of actual pain.	But little if any relief.	Not stated.	Poor health (syphilitic). Acute exacerbation of an otitis med. pur. of two months' standing. Four days after first incision, which in the mean time had healed, pain again became severe. Made a second and very free incision through posterior half of membrane. During following ten days, three more incisions, each one affording only temporary relief. Permanent relief was finally obtained after an incision had been made through the mastoid integuments, and, still later, one through the skin lining the external auditory canal.
32	5	Not stated.	Red and swollen.	Not stated.	14th	Not known.	Not stated.	Patient did not return.
33	40	Not stated.	Red, parched, and slightly bulging.	Tender	3d	Immediate.	36th	Two days later pain returned, though with less severity than before. On seventh day of attack made a second incision. Relief from pain lasted twelve days, when, the perforation having nearly healed, the pain returned. It was not severe, however, and may have been due to a furuncle in the meatus. After this, rapid and complete recovery.
34	7	"Cold in the head."	Bulging posteriorly.	Not stated.	2d	Speedy.	Not stated.	
35	30	Not clear.	Red and swollen.	No tenderness.	4th	Relief in 1 or 2 hours.	5th	
36	4½	From use of post. nasal syringe and salt water.	Red and bulging.	No tenderness.	3d (a mere prick).	Only slight relief.	Not stated.	On fourth day, I made a free incision through the posterior half of membrana tympani. Entire relief in a few hours.
37	11	Not clear.	Red and swollen.	No tenderness over mastoid but some over occiput.	20th	Very little until after 48 hours.	Not stated.	

No.	Age	Cause.	Condition of membrana tympani.	Condition of mastoid region.	Day of disease on which paracentesis was performed.	Relief from pain.	Day of disease (approx.) on which perf. healed and otorrhœa ceased.	Remarks.
38	7	Not known.	Red and swollen.	No tenderness.	3d or 4th	Not ascertained.	Not ascertained.	Patient did not return to the Infirmary.
39	42	Not known.	Red and swollen.	No tenderness.	14th	Not ascertained.	Not ascertained.	Patient did not return to the Infirmary.
40	24	Not known.	Post. half bulging: small perf. in ant. half.	No tenderness.	15th	Speedy relief.	Not stated.	
41	5	Not known.	Inflamed and swollen.	Not stated.	Not ascertained	Not ascertained.	Not ascertained.	Patient did not return to the Infirmary.
42	54	Blow on the ear.	Post. half red and bulging.	Tender on pressure.	About 30th	Not ascertained.	Not ascertained.	Patient did not return to the Infirmary.
43	14	River bathing	Much inflamed.	Not stated.	5th	Not ascertained.	Not ascertained.	Patient did not return to the Infirmary.
44	24	River bathing	Congested and uneven.	Not stated.	About 25th	Very little relief until 2 days later.	About 48th	Second incision on fortieth day, the pain having returned.
45	47	"A cold."	Red and bulging; small perf. anteriorly.	Tender on pressure.	8th	Almost immediate relief.	Not ascertained.	Pain returned next day, and on the eleventh day, the membrana tympani being again in a bulging condition, I made a second and free incision. Leeches applied at same time to mastoid region. Patient did not return to the Infirmary.
46	16	Not stated.	Red and swollen.	Not stated.	8th	Pain soon subsided.	14th	Pain returned on the eleventh day, and was relieved by leeches. It returned again on the thirteenth day, and was again relieved by leeches. Rapid recovery afterwards.
47	22	Not stated.	Red and swollen.	Not stated.	5th	Relief in a few hours.	In the course of a few days.	
48	38	Caught cold.	Red and bulging, especially posteriorly.	Not stated.	5th	Relief in a few hours.	13th	
49	3	Acute nasal catarrh	Red and bulging.	No tenderness.	2d	Relief in a few minutes	4th	A year later the incision was repeated in the same ear, under the same circumstances, and with equally beneficial and speedy results.
50	6	Not stated.	Red and bulging.	No tenderness.	8th	No relief until 24 hours later, when a discharge appeared.	Not stated.	High fever, apparently total deafness, and symptoms of general meningitis at time of making the incision. The other ear also involved.
51	25	Not stated.	Red, diffusely swollen, and œdematous.	No tenderness.	8th (leech's having failed to give relief)	Entire relief in a few hours.	14th	
52	34	From use of nasal douche.	Œdematous and slightly bulging.	No tenderness.	2d	Relief in a few hours.	3d	
53	35	Not stated.	Red and bulging.	No tenderness.	3d	Relief in less than an hour.	15th	Leeches failed to give relief on second day.
54	63	Not stated.	Red and bulging posteriorly.	Tender on pressure.	4th	Marked relief in a few minutes.	About 65th	
55	50	Unknown.	Red and bulging; perforation anteriorly.	Not stated.	10th	Not ascertained.	Not ascertained.	Leeches also applied. Patient did not return to the Infirmary.
56	21	River bathing	Diffusely swollen.	Not stated.	About 50th	No decided relief until 48 hours later.	About 64th	Abscess formed behind the ear and was opened by an incision. By the sixty-eighth day, the abscess had also healed.
57	20	Not stated.	Not stated.	Not stated.	8th	But little relief.	Not ascertained.	Second incision on the eleventh day. Patient did not return afterwards to the Infirmary.
58	22	Not stated.	Not stated.	Not stated.	6th	Marked relief in a short time.	Not ascertained.	Second incision on the ninth day, the pain having returned, and the discharge having ceased. Patient did not return afterwards to the Infirmary.

ON THE BEST MEANS OF TESTING THE HEARING.

BY

CHARLES H. BURNETT, M.D.,

AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

In the following paper I shall endeavor to give a sketch of the known relation of hearing to the watch, the tuning-fork, and speech, the generally accepted tests. After a consideration of normal hearing, it shall be my aim to show how the diseased ear is affected by these tests, and wherein they give information as to its state, and wherein they fail to do so. Afterwards, a conclusion may be better arrived at as to the best form of test or tests for the hearing. It will be necessary to review the writings, discoveries, and opinions of leading physiologists and aurists of the last two or three decades, and by this means the ground of the best labors will be fully gone over. Nothing is promised as original on my part; rather shall it be my aim to bring together, at such a time as this, the doings of others, as impartially and completely as lies in my power.

No precise standard of normal hearing has been defined. The normal ear hears all sounds which fall upon it; but it cannot be said, *à priori*, where good hearing ceases and defective hearing begins, for, in many senses, *hearing* is a relative term. Just as there is an average standard for the amount of food, excretion, etc., there might be an average standard for hearing. The sense of hearing must be regarded as composite, consisting as it does of the ability to perceive not only a great variety of sounds, musical or periodic, but also those which are irregular or noisy. All such sounds can be heard singly or together. Hence, the sense of hearing may be said to lie in a collection of elements, largely nervous, which can be aroused singly or together. The mere fact that more than one sound can be heard at the same time, shows that the organ of hearing is composed of a number of structures arranged so that each can receive its definite impression.

The Watch.

Some form of watch-work, or ticking apparatus, has been used a long time as a ready means of testing the hearing. In this way the pocket-watch, mantel-clock, metronome, or an especially contrived, ticking machine, has been called into requisition. Such a test has usually been all that has been deemed necessary, and in many cases has seemed to satisfy both patient and physician as to the amount or state of hearing. Gradually, as the anatomy and physiology of the internal ear became better known, the idea arose of assigning to the cochlea the hearing of music or musical notes, and to the rest of the labyrinth, more especially to those parts in the vestibule, the perception of noises or irregular vibrations. When this theory obtained currency, the watch was classed

among noises and not musical sounds, though its beats were regular in their occurrence.

Be this theory of the physiology of the two parts of the internal ear false or true (it is not my province nor intention to review or criticize it here), Oscar Wolf has shown that the tick of a watch is a low form, if I may use the term, of musical note, with a not easily determinable pitch. Its impulse, therefore, cannot produce irregular waves of sound. All watches, metronomes, and the like, must therefore be classed under the head of instruments producing musical tones, and of course each watch, ticking apparatus, etc., has its own peculiar pitch. But at best these instruments give out but two notes, of short duration, and decidedly poor in harmonics.

This accounts for the inferiority of the watch, etc., as a test for hearing, and also explains why some affected ears appear to hear the watch better than others, and also why it is that there is so much difference in the relative manner of hearing the voice and watch, on the part of those hard of hearing.

According to Wolf, the tick of a watch should not be classed under noises, for it is really a musical sound with very high overtones, the short duration and intensity of which fall in a few seconds from their maximum to nothing. "With the ticking of a watch, we test the patient with but two tones out of the whole scale, and those neither very pure nor precise. The hammer or anchor strikes upon the cog-wheel, and by its impact calls forth two weak tones, which are somewhat intensified by the resonance of the watch-case. The pitch of these notes is not easily determinable; the intensity is measured by the observer according to the average distance at which persons of normal hearing are able to perceive the tick."[1] This has proven very unsatisfactory as a test, because it is often found that a watch is heard relatively better or worse than the voice, etc. This is very easily explained when we reflect that with the watch we have only tested the power of the ear to hear two relatively weak and impure tones. Wolf therefore says: "Should it happen that the patient has a disturbance of the nerve-fibres corresponding to these two tones, it is conceivable that, while absolutely deaf to the ticking of the watch, he may hear other far weaker tones which hold a different position in the scale, and, on the other hand, that the patient may hear the ticking of the watch at a relatively greater distance, and at the same time misunderstand certain spoken words, and even loudly spoken tones."

Such a disturbance of fibres in the nervous apparatus of the ear most likely happens even with the diseases of the middle ear, for Politzer[2] has shown that the tympanic vessels are connected most closely with the vessels of the cochlea; hence, tympanic disease is more than likely to bring about labyrinthine disease. Therefore, the above test is just as applicable in diseases of the tympanum as when the disease is primary in the labyrinth.

The Tick of the Watch or Clock.—Even a child will tell us, "The clock says tick, tock;" to its ears, therefore, there are in the sound made by the watch, vowel sounds of "i" and "o," and consonant sounds of "t" and "ck." Now, vowels and consonants are musical notes of certain, definite pitch, and therefore it may be said that even in this simple way a watch-tick is musical. This view of the watch-tick, viz., that it is an alternation

[1] Archives of Ophthalmology and Otology, vol. iv. p. 69.
[2] Correspondence with the writer, 1876.

of two notes simply, would explain in a measure why one clock is heard better than another by an affected ear. For, even when the intensity is the same, one watch is apparently heard better than another. This is due to the fact that the pitch of one appeals more strongly than that of another, to the ear which is being tested.

The Stop-watch.—Of all forms of ticking apparatus, the stop-watch is the most useful. Besides its power as a test, we also possess in it a means of finding out whether the patient really hears the sounds of the watch, or whether he thinks he does because he knows a watch is being held near his ear. This means has often been the first to declare that the patient's statements respecting his subjective state are not entirely reliable. Such occurrences, while testing with the watch, serve to show how unreliable this apparatus is, as must be all tests in the use of which the surgeon must accept the patient's statement alone, as to how much is perceived. Not only are adults of the greatest intelligence and fairness of intention sometimes utterly self-deceived by the watch-tests, but children as a rule give entirely unreliable statements respecting their ability to hear a watch. This, of course, is perfectly well known to all aurists, and I am sure that they have long ago concluded that accuracy in the use of any form of ticking apparatus can only be obtained by the employment of some form of stop-watch, since by this means they can find out whether a patient really is aware of the going or the stopping of the ticking.

Some observers have gained a similar end by alternately holding and removing a diaphragm of paper between the ear and the watch. In some instances, even while the ticking continues, the patient who has been hearing it will state that he now no longer hears it. This may be a perfectly true statement, and is explained by the fatigue of the ear. Every one must have noticed that in some forms of chronic aural catarrh the ear seems to lose its power of accommodation, or, as one may say, the power of continued listening. This has been specially noted by some writers (Weber-Liel and others), and is explained as being due to a failure in the muscular functions of the middle ear. It appears not only when testing with a watch, but also with speech. It is more likely to occur with a watch, however, because of the sameness of the test note, and the consequent continued use of the same parts of the hearing apparatus. Hence the watch may be a better test for this condition of the ear than the more variable vocal sounds, since the latter, playing up and down a series of notes, allow momentary rest of some parts of the ear, while others are being called into action.

Not only can the smallest amount of hearing be detected by means of a loudly ticking watch, but the same means may aid in prognosis in chronic diseases. The watch which I have found preferable, can be heard from 50 to 60 feet. If this watch is heard by a patient only a few inches, I feel obliged to give an unfavorable, or at best a guarded, prognosis as to the recovery of hearing. In such a case of excessive impairment of hearing, the loudness of the watch rather than the pitch of its note is to be considered, for if the ear cannot hear such intense ticking as that alluded to above, it certainly cannot retain much of its function. In such cases, a small pocket-watch would be useless, for not only can it not be heard by a very defective ear, but even an ear far from being very deaf cannot hear the faint sounds of a watch. Hence the intensity of the sounds of a ticking apparatus is of more importance than the pitch of its poor musical tone.

The Use of the Watch in Bone Conduction.—The watch is heard, *per ossa*, poorly by most persons over fifty years of age. Hence, it must be expected that the young will hear the watch much better by bone conduction than the old. Bearing this in mind, the ticking apparatus, of whatever form it may be, will generally give some clue to the state of bone conduction in our patients. But the usual weakness of its vibrations will interfere with its value as a test in this respect. The tuning-fork, however, is able to communicate its powerful vibrations through the bones of the head to the auditory nerve.

Conclusions respecting the Watch.—It may, therefore, be said that the watch, being a low form of musical apparatus, giving out one or at best two notes, poor in harmonics and lying near each other in the scale, is a test of only limited value. It may, however, be of great use, if its intensity is increased, in judging of the quantitative hearing in a given case. In very defective hearing, it is to the small amount of hearing still remaining what a lens is to a small object, for it enables the surgeon to find out if *any* hearing be present, and about how much. As a test for bone conduction its value is limited, both by the age of the patient and by the weakness of the notes. Although of some value in this respect, it falls far below the tuning-fork as a test for the sound-conducting power of the bones of the head.

The Tuning-Fork.

Little, if anything, has been added to our knowledge of the use of the tuning-fork in aural diseases since Politzer wrote his papers on this subject in 1868.[1] Dr. Urbantschitsch, of Vienna, has pointed out what he calls the deaf points (*tauben Punkte*) of the normal ear. These "deaf points" he discovered while experimenting with the small tuning-fork, passing the latter to and fro past the ear. Any one can satisfy himself on this matter by simply passing a small tuning-fork, with the line of the vibrating tines at right angles to the side of the head, backwards and forwards in the plane of the auditory canal. A point will be reached where suddenly the sound fades or disappears, to be heard again when the fork is moved either way from this point. This is purely physiological, and should be borne in mind in testing.

The tuning-fork, like the watch, may be used in two ways as a test: (1) By the air, aerial conduction: this is a test applied to the sound-conducting apparatus and secondarily to the nerve; (2) By the bones of the head, bone conduction: a test applied primarily to the auditory nerve, and secondarily to the sound-conducting apparatus. For the fork thus used shows whether sound can be conducted away from the ear in a given case, or whether, being impeded in their escape from the sound-conducting parts, the sound-waves are thrown back on the perceptive part of the organ.

If the note of the fork be not very loud, and if the tines of the instrument be properly clamped, the sound will not be heard further than a few inches from the ear. Thus one ear can be tested through the air, without risk of participation in the test on the part of the opposite organ. In addition to this advantage, a tuning-fork of low note and with well clamped tines, when used alongside the ear, cannot be heard through the

[1] Wiener med. Wochenschrift.

bones of the head. For these reasons a tuning-fork is of value as an aerial test. But, while highly musical, it has the great disadvantage, like the watch, of giving out only one note at a time, which may or may not be heard relatively better than another note by the affected ear, and therefore, like the watch, the tuning-fork is of limited usefulness as a test.

In order, therefore, to derive a wide advantage from the tuning-fork, one must either be at the inconvenience of shifting the clamps on a single fork, or else possess a large number, permanently graded in their pitch. Such a set of forks, to be of real value, must be most carefully graduated in order to correspond with the power of the ear to perceive the intervals between musical notes, otherwise certain fibres of the organ of hearing will be left out in testing. Such a set of tuning-forks for testing is not only difficult to obtain, but extremely costly. The tuning-fork, therefore, though possessing many excellent qualities as a musical test, through the air, is limited in its practical application.

It may be stated, as an axiom, that the normal ear hears the tuning-fork better through the air than through the bones of the head; but chiefly in the latter way has it been used as a test.

According to Politzer, E. H. Weber first settled the point that a vibrating tuning-fork, in contact with the bones of the head, was better heard in that ear the external auditory canal of which was stopped by the finger. This phenomenon was long unexplained, until Mach, on purely theoretical grounds, advanced the view that the reason of this lay in the hindrance offered by the finger in the auditory canal, to the escape of the sound-waves from the ear. Politzer, having in mind this phenomenon, thereupon made a series of experiments upon the human ear, and came to the conclusion that the above-named, augmented perception of sound, upon closing the external auditory canal, was due to (*a*) the reflection of sound-waves from the bones of the head through the air of the external auditory canal to the membrana tympani and auditory ossicles; and (*b*) to the hindrance which the sound-waves, passing from the bones of the head to the labyrinth and tympanic cavity, met in escaping from the ear. In the latter conclusion he was in entire agreement with Mach.

If hearing a tuning-fork better on the deafer side is due to hindrance of the escape of sound-waves, even while the external auditory canal is open, stopping up the latter with the finger should increase the sound of the tuning-fork. Dr. Roosa[1] is of the opinion that if closing the auditory canal by the finger does not increase the hearing of the deaf side, it is a sign that the nerve is affected. The late Mr. Hinton,[2] of London, was inclined very strongly to the view that, when for other reasons he could diagnose a nerve-affection on the deaf side, an increase of hearing for the tuning-fork by stopping the deaf ear, was confirmatory of the presence of disease of the auditory nerve. Politzer has shown (*loc. cit.*) that a nerve-affection may exist on the deaf side to such a degree that the delicate noise of a ticking watch is not heard better on the deaf side by bone conduction as long as the auditory canal is left open, but that by increasing the quantity of sound made to impinge on the nerve through the bones of the head, either by stopping up the auditory canal and forcing more sound from a given source, as when using a watch, or by increasing the original amount of sound employed in the test, as

[1] Treatise on the Diseases of the Ear.

[2] Questions of Aural Surgery.

when a large tuning-fork is used, then the diseased nerve, which is too weak to reply to a small amount of sound, is stimulated into action by the greater amount of sound-waves thrown on it. By remembering this latter fact, the views of Roosa and Hinton are made to appear less at variance than they seem at first sight, for the correctness of the theory of each of these distinguished observers is dependent upon the amount of nerve-disease, since it will be found that Dr. Roosa is correct if the nerve is paralyzed, and that Mr. Hinton's theory is right if the nerve still retains some of its power.

In alluding to sound-conduction through the bones of the head, Moos says: "We have in it one of the *most important* means of making a diagnosis of disease of the internal ear." He recalls the fact, already pointed out by Johannes Müller, that, in cases of bone conduction, conveyance of sound through the auditory ossicles and through the air must not be lost sight of. "Since in every case of bone conduction, *i. e.*, in cases where the vibrating tuning-fork is placed on the vertex, or brought in contact with the bones of the head, sound-waves pass into the ear in these two directions, the tuning-fork cannot be used in this way as an infallible means of making a differential diagnosis between diseases of the labyrinth and diseases of the middle ear; for it is well known by experience that the tuning-fork fails to aid in cases of well-known disease of the labyrinth, as well as in those of disease of the middle ear."[1]

Three-limbed Auscultation-Tube.—To confirm or correct the patient's statements, there has been advised the use of a three-limbed auscultation-tube,[2] two arms of which are to be placed in the auditory canals of the patient, and the third in the ear of the observer. If now a vibrating tuning-fork be placed on the vertex of the patient, the auscultator can perceive the sound of the fork, streaming from the ears of the patient. By alternately pressing the two arms of the apparatus connected with the patient's ears, the auscultator can learn from which ear the greater amount of sound comes. It seems but natural to suppose that more sound-waves must come from the less obstructed ear. The latter will, as a rule, be the better hearing ear, unless its fellow be deaf, not from obstruction in the sound-conducting parts, but from paralysis of the auditory nerve.

The Interference-Otoscope.—A similar instrument, though one used in a different way from that just mentioned, has been devised by Prof. Lucæ,[3] of Berlin, and is named by him the interference-otoscope. This instrument consists of a double stethoscope of Scott Allison, the limbs of which, intended to fit snugly into the auditory canals of the patient, are eleven Paris inches long. At the junction of these symmetrical arms is placed a T-shaped, glass tube, from the portion of which representing the standard of the letter, passes a rubber tube to a collector of sound, half paraboloid in shape. Here the vibrating tuning-fork is placed. To the other end of the cross piece of glass tube is fixed the rubber tube, two feet long, for the auscultator. Lucæ's experiments in this direction were based on the fact that sound-waves, falling on a stretched membrane, are only partly taken up and transmitted by it. The supposition then naturally follows that sound-waves entering the external auditory canal are only partly transformed into the peculiar, pendulum-like, to-and-fro movements of the sound-conducting membrana tympani and

[1] Klinik d. Ohrenheilk., S. 41. [2] Moos, op. cit., p. 42.
[3] Archiv für Ohrenheilk., Bd. iii. 1867.

the ossicles. According to the greater or less extent to which the membrana tympani takes up the sound-waves falling on it, this so-called reflection of the waves of sound will vary in amount. The investigations made tend to elucidate experimentally this reflection, and the probable influence on it of the changes of tension in the sound-conducting apparatus; also, from a study of these phenomena of reflected sound-waves, the endeavor is made to obtain an objective expression of the sound-waves taken up by the ear.

Physical Experiments.—Physical experiments show that (1) A stretched and inclined membrane of India-rubber, placed in an artificial ear made to represent as closely as possible the natural organ, will reflect a certain quantity of the sound-waves entering the external auditory canal; (2) Closure of the Eustachian tube increases slightly this reflection; (3) Increased tension of the membrane shows that the reflection is directly proportional to the tension; (4) This outward reflection of sound-waves is greatest whenever the tension occurs simultaneously with considerable changes in the density of the air contained in the tympanic cavity.

In order to make practical application of these laws, Dr. Lucæ devised his interference-otoscope, by which the relative amounts of reflection from both ears, it is claimed, can be determined. The results obtained in the normal ear, by the use of this instrument, are thus given: (1) The normal organ of hearing reflects a certain amount of the sound-waves entering the external auditory canal; (2) The reflection increases in all changes in the sound-conducting apparatus, especially those in the middle ear, which lead directly or indirectly to an increased tension of the membrana tympani; (3) The examination of persons with normal hearing, by means of the interference-otoscope, shows that the different sensibility of both ears, for the same tone, is caused by the different amounts of reflection brought about by different tensions in the two sound-conducting apparatuses. Respecting the diseased ear, the conclusions are: (1) The interference-otoscope shows in the majority of cases of disease, in analogy with the observations made on those with normal hearing, a *greater* reflection from the diseased ear; (2) This is found in a number of cases in which the ear-mirror and the catheter reveal a disease in the external or middle ear; (3) In the numerous cases of ambilateral chronic catarrh of the middle ear, without perforation of the membrana tympani, the examination usually reveals a *greater*, though often a *less*, reflection from the worse ear; in the latter instance a simultaneous disease of the labyrinth may be supposed, and the prognosis becomes by far less favorable; (4) The greatest worth of the method lies in the not uncommon cases in which all other diagnostic means fail to show morbid changes in the external and middle ear; here too, as a rule, a stronger reflection is observed on the worse side, which points to a deep-seated disease of the sound-conducting apparatus. Only in some few cases does the examination reveal a less reflection from the worse ear, in which cases a primary disease in the labyrinth may be assumed with great certainty.

Tuning-Fork Vibrating on the Parietal Protuberance in a Normal Case.—If a vibrating tuning-fork be placed on either parietal protuberance of a person with normal ears, it will usually be heard in the opposite ear. This is most easily perceived when a large fork of deep and heavy note is used. This phenomenon, if it may be so termed, will often lead to confusion in diagnosis, inasmuch as the examiner would at first expect the fork to be heard best in the ear nearest to which the fork is placed.

As it is heard best in the more distant organ, a conclusion might be made that the latter ear was diseased in its conducting parts. Care must, therefore, be taken to have the vibrating instrument in the central line of the head, either on the vertex or glabella, or held between or on the teeth. An explanation of the above is perhaps most satisfactorily sought for in Dr. Lucæ's[1] demonstration that vibrations which fall perpendicularly on the membrana tympani produce much the strongest vibrations, and that hence a tuning-fork placed on the parietal prominence, or the side of the head, will be chiefly heard in the opposite ear. According to Dr. Lucæ, this is best perceived when the meatuses are stopped. But it can also be perceived, as any one can find out, with perfectly open meatuses.

Conclusions respecting the Tuning-Fork as a means of Testing and Diagnosis in Diseases of the Ear.—It has been shown that the tuning-fork has a twofold use: (*a*) as a test through the air, and (*b*) as a test through the bones of the head; *i. e.*, it is a test of the sound-conducting power of the ear, and also of bone conduction of sound to the auditory nerve, and of the perceptive power of the latter. In the first instance, its advantages are that one ear may be tested without communicating the sounds of the fork to the other ear, since a properly clamped fork cannot be heard far enough when held before one ear to be perceived by the other. The disadvantage in the tuning-fork is that it gives only one note at a time, and, therefore, testing with that gives no information respecting the ability of the ear to hear other notes. Its applicability, therefore, is limited. Various notes may be produced by the same fork by clamping the tines at different points. But this necessitates some delay.

The tuning-fork finds its greatest usefulness in testing bone conduction. While it has never fully realized in this way all that was hoped for it, as an aid in diagnosis, it is still the best means, and a very good one too, of determining how much sound is conveyed to the auditory nerve through the head-bones. Its musical nature, as well as its powerful vibrations, render it far superior to the watch as a test for the conducting power of the head-bones, unless the ticking of the watch is made to occur with great force. But should the ticking of the watch equal in intensity the vibrations of the fork, the former could never approach the latter in musicalness. The tuning-fork is a means of comparison between the bone conduction and aerial conduction of sound in the same person; for if the vibrating tuning-fork be held on the vertex until its note is no longer perceived by the person examined, and then held before his ear, if he now perceive that the fork is still vibrating, it is fair to conclude that the sound-conducting apparatus is normal; but if the fork, when no longer heard through the air before the ear, be heard as soon as it touches the vertex, the conclusion is inevitable that there is some impediment in the sound-conducting part of the ear. This is all the more convincing if it be borne in mind that there is being used the same note, and one, too, growing a little weaker all the time, because, if vibrations of a tuning-fork cease to be heard in front of an ear by aerial conduction, but are able to communicate themselves while growing constantly weaker, through the bones of the head, the inference of great derangement in the middle or external ear (aerial sound-conducting parts) cannot be avoided.

Bone conduction, however, is of little importance to the patient, and of great uncertainty as a guide to the aurist, because he is forced to rely

[1] Berlin klin. Wochenschr., No. 10, 1871.

almost entirely on the patient's statements as to what is perceived by the latter when the test is applied. Therefore, the tuning-fork as a means of testing bone conduction can never become of pre-eminent value. At best, it must be used in conjunction with other tests, and its results carefully weighed. Then, too, the musical education of the patient most probably influences his answers respecting the sensations produced by the tuning-fork vibrating on the vertex.

Speech.

By hearing speech, the intellectual development of the human being is accomplished. There is no sound so familiar, nor so fondly longed for at times, as the sound of the mother-tongue. A person with good hearing can never realize the feelings of a deaf person so vividly as when travelling in a strange land, surrounded by those speaking with each other happily, gayly, and with varying expressions, but in a language unknown to the lonely traveller. One falls into the position of an invalid, is treated with a kind of pity, and, alas, finds himself growing a little suspicious and morose.

The deaf person feels the loss of hearing the voice of others more than the loss of the power to hear anything else. To recover the ability to hear the familiar tones of the voices of his friends, he would gladly give up all other hearing. So great is this struggle to hear what others say, that the deaf gradually learn to understand the thoughts and words of others by watching the lips of the speakers. The power to hear other sounds well, may begin to fail without the knowledge of the patient, but all his endeavors are concentrated, almost unconsciously, to catch the varying sounds of speech. I have known young physicians to be almost deaf to the ticking of a watch without knowing their loss until it was accidentally discovered, for their ability to hear speech was retained. All aurists are aware that patients are constantly surprised to learn how *deaf* they are, as soon as their faces are averted from the speaker. Thus the failure of hearing, in this respect, is detected very often, for the first time, in the summer, when all are used to sitting either on the porch or in the parlor, in the twilight and dark. As the light fades, and the faces of those around are no longer plainly visible, the hitherto apparently hearing person becomes aware that he is deaf. This is often assigned to the night air, but, in reality, it is due to the loss of vision in the approaching darkness. The surgeon will often gain great aid by a knowledge of these facts, and also by observing the manner in which a partially deaf person will look at the one he is addressing, and from whom he expects a reply. Those of delicate sensibility soonest become aware of their inability to hear the voice, for speech is not only a delicate sound, but is highly valued by the cultivated. Those of less sensibility are not aware of their loss of hearing speech, for they still hear loud sounds and even music, as the latter is more powerful than the notes of speech. Hence, it is surprising to find how large an amount of unconscious deafness exists in the uneducated; they do not feel their loss as the cultivated do.

Very often the deaf are, in a measure, unaware of their aural condition, because they feel, instead of hear, so many sounds. Roosa has found that the deaf and dumb may hear, *i. e.*, feel, at the diaphragm, a tuning-fork vibrating on the vertex. A man who had been struck on the head, and in consequence had become totally deaf, informed me that

he could *hear* a tuning-fork vibrating on his vertex. This I doubted: I believe that he merely *felt* the vibrations. Whether he heard them or not, he could not hear the loudest shout into his external ear. The loss of hearing speech was his great misfortune; this he desired to recover; and in his case *speech* became the great test. The tuning-fork was valueless because unreliable.

The human voice was considered an admirable quantitative test, long before the researches of Donders, Helmholtz, and Wolf, showed it to be equally valuable as a qualitative test. Why it was that a patient could hear some words much better than others, though spoken at the same distance, was not explained and applied until O. Wolf published his investigations into the acoustic characters of the various elements of speech.

The human ear perceives as musical sounds, tones varying from 16 vibrations to 20,000 vibrations in a second. Preyer (Jena, 1876) has lately placed these limits from 15 vibrations to 40,960 in a second. Speech embraces only eight octaves, according to Wolf,[1] viz., "R" with 16 vibrations, and "S" with 4324 vibrations in a second. In music, the most agreeable notes, with the most distinct pitch, lie between 40 and 4000 vibrations per second, *i. e.*, within the limits of seven octaves; those which are admissible in the widest sense as musical, lie between 20 vibrations and 38,000 vibrations per second, *i.e.*, within eleven octaves.[2] In this respect the ear far outstrips the eye, for the limit of the perceptive power of the eye for vibrations of light rarely exceeds one octave.

Blake's experiments[3] with König's rods, have shown that the human ear, in some instances, hears distinctly, as musical, 35,000 vibrations in a second. The ability to hear these very high notes is greater in youth (12 years) than in older persons. The former may distinctly hear a note of 40,960 vibrations per second, at a distance of 34 feet; from 18 to 20 years of age, this note is heard only at 13–16 feet; and at the extreme limit of 34 feet, only the tone of 36,864 vibrations per second is heard. This ability to hear high notes greatly diminishes as age advances. Dr. Blake says: "In the majority of the cases of persons over fifty years of age, and possessing apparently normal hearing, who were subjected to these tests, an examination of the membrana tympani showed a varying degree of opacity of the membrane, corresponding to a thickening of the mucous coat." All such sounds were heard much better when the membrana tympani was perforated, especially near the posterior superior periphery. In one case, where a small band of cicatricial tissue extended from the posterior border of the perforation to the long process of the incus, a tone of 65,536 vibrations per second was distinctly heard.

Wolf's Determinations respecting Hearing, Voice, Vowels, Consonants, etc.—According to Wolf,[4] it is impossible to establish the distance at which the separate vowels can be heard, because the sound-sources from the speaker and the hearing of the listener vary in different individuals, and also because the sound-waves are so dependent upon the condition of the atmosphere in which we are placed. At night we hear much further than by day, because the ear is less distracted by a multitude of sounds, and because there is a much less number of sound-waves crossing each other than in daytime. (1) Vowels are endowed with the greatest strength of tone, *i. e.*, they are heard and understood at a distance at

[1] Sprache und Ohr, 1871.

[3] Trans. Amer. Otolog. Society, 1872–1873.
[4] Op. cit., p. 58.

which all the consonants are inaudible; and (2) The consonants differ very greatly in the strength of tone.

(1) *Vowels.*—Vowel-sounds are composed of a number of beautifully harmonic overtones, which accompany the fundamental note, and strengthen the fundamental tone of the mouth. A good musician can hear a perfect accord when a vowel-sound, especially "A," is uttered with clearness, which is said (Wolf and Appunn) to be specially observable when the sound is made in the open air, where the sound-waves can escape with greater precision than in a room. "A" (German, broad) has the most overtones, five, and is heard the furthest, *i. e.*, at 360 paces (Wolf). The vowel "U" ("Oo," English) has the fewest overtones, three, and is heard with most difficulty of all vowels. It can be distinctly heard only at 280 paces. The vowel "O," containing many beautiful harmonic overtones, is heard nearly as far as "A," broad. German "E" (English "A") is heard at 330 paces; German "I" (English "E") is heard at 300 paces; English "I" is somewhat more powerful than English "A," and weaker than broad "A" or "O"; "Oi" comes close behind "E"; the weakest of all diphthongs is "Ou," as in *out;* it is a little stronger than "Oo."

(2) *Consonants.*—The investigations of Wolf have led him to classify consonants according to their acoustic and physiological laws, under two heads, viz., those which are self-sounding (*selbsttönende*), and those which are sound-borrowing (*tonborgende*). The former class embraces those sounds which are formed by the apparatus of the oral cavity, with a sound which is independently audible, and which can be defined in its pitch, intensity, and timbre. The second class comprises those consonant sounds which attach themselves to a vowel-sound, and are obliged to borrow from it in order to be distinguished by the ear; musically they are to be termed the appogiatura, and note of complement to a vowel sound; such consonants are H, L, M, N, W.[1]

"H" is the weakest of all consonants when pronounced without a vowel. It is lost at the distance of a few paces. Next in strength stands "B"; "Ba" is heard further than "Ha." "B" alone is heard at a distance of 18 paces. The deeper a note is, the less effect it has upon the ear. "R," with only 16 vibrations in a second, is not distinguishable further off than 41 paces. "K" and "T" stand next; they are both heard about equally well at 63 paces. "T" resembles pretty closely a simple note, but it has a pitch which appeals more readily to the ear, and is therefore much better heard than "B," which otherwise is very similar to it. "K" is formed with relatively favorable circumstances—that is, by means of a powerful movement of the root of the tongue. The soft "F" is heard somewhat further than the foregoing letters, *i. e.*, at 67 paces. "S" is perceived at a relatively greater distance than the foregoing on account of the pitch of its fundamental note, which appeals to the ear by its sharp character, especially when sharply pronounced; and finally on account of its properties as a sibilant consonant. "To this latter property it owes its ability to express disapprobation in public assemblies, to cry down opposing sentiments, and to enforce silence. Both its moral use and physical character are inharmonic." "S" can be heard very distinctly at 170 paces. "Sch" is heard furthest of all consonants, because it possesses a full and rich clang-tint, and is composed of three harmonic notes, which predominate, while the inharmonic overtones or noises recede. The composite conso-

[1] See Wolf, Archives of Ophthalmology and Otology, vol. iv. p. 78.

nant "Sch" (nearly = "sh") can be heard at 200 paces. "M" and "N," unaccompanied by vowels, are only meaningless blowing of air through the nostrils. "Mama" and "Nana" are understood at 180 paces, but at greater distances the sounds of "M" and "N" are lost, while the vowel "A" is still heard.[1] In calm weather it is extremely interesting to ascend a high hill and listen to the voices of men below in the valley or town. Words are no longer distinguishable, or, at best, only those which are composed of "M" and "N" and vowels, as "Mama," "Nein," etc. Vowels in all the other words are distinctly heard, following each other in a curious interchange and with remarkable cadences, because we are no longer able to join them together into words and sentences.[2]

It is thus shown that in the component sounds of ordinary speech, a wide range of tests, with different intensities of sound, is offered to the aurist. Such a numerous set of sounds is needed in order to discover which are heard best by an affected ear. One sound is not sufficient, because an ear may be unable to hear some sounds while it hears others comparatively well. Hence if only one or two sounds should be employed, as in the watch, just those notes, it might be, the ear could not hear as well as others. Therefore, speech becomes most valuable, because it is very varied in sound-nature, and also because it is ever at the command of the aurist, and the use of it is fully comprehended by the patient. If one sound would do as a test, a sound-unit could be established; but it is seen upon short experience that a solitary and fixed sound is not heard in the same way by all similarly affected ears, and that, therefore, one sound cannot be assumed as a fair test. This throws the surgeon back on speech, as containing a variety of sounds, by means of which an average condition of the ear can be ascertained.

Very often whispers and words spoken in low tones are heard much better than loudly spoken words, by an affected ear. This is due to the damping of the vowels, whereby the consonants, which are less sonorous, have a chance to be heard. And thus it is that a person hard of hearing often asks not to be addressed loudly. Words may be heard, even when the letters composing them, spoken separately, are not heard. This is especially so for the letters B, P, T, K, and R (Wolf). The reason of this is very apparent, for when letters are pronounced alone, they are words. Thus "B" is composed of sounds of "b" and "e," "P" of p e a, or p e e, "K" of k a y, while "R" is equivalent to sounds of a r e. In the latter instance, "R," when pronounced, is altogether of a different phonetic value from that which it has when standing at the beginning of a word, as in "rat," or at the end of a word, as in "tar." Whispering has an advantage over loud words in testing, since the former cannot be as easily conveyed as the latter through the bones of the head, to the auditory nerve.

However, it must be borne in mind, that in Dr. Dennert's observations[3] made in a case in which the cochlea had been lost by necrosis, the normal ear, though artificially stopped up as thoroughly as possible, could yet hear whispers at a distance of six feet. Patients often state that they hear music either of a piano or of an orchestra, but that they cannot hear speech. This is due to the delicacy of the sounds of the human voice in speech. The most delicate sounds of a violin are far more powerful than

[1] Wolf, loc. cit., p. 63. [2] Helmholtz, Tonempf., S. 118.
[3] Archiv f. Ohrenheilkunde, Bd. x.

speech, and hence the ability of those hard of hearing to perceive instrumental music much better than the component sounds of speech, as has been shown by Wolf.

Variable Hearing.—In some cases of chronic aural catarrh, the statement that the hearing varies with the weather, health, etc., is made by the patient. This is not always demonstrable, nor, if so, are the variations in hearing very striking. But in some other forms of aural disease, variable hearing occurs in a marked degree, and may lead to a knowledge of the nature of the disease. There are not many cases of the kind I allude to, recorded in aural literature. I have observed two cases; one in which the hearing varied greatly with the position of the patient, being least when he was in the upright position, and greatest when he lay down. This variability was due to movements of fluid in the tympanum.[1] The other instance of variable hearing occurred in a well-marked case of acute aural vertigo, presenting features which, like those in a case related by Hinton,[2] naturally led to the conclusion that the disease as well as the variable hearing was due to derangement in the muscles of the tympanum; for the attacks of vertigo were ushered in by the onset of tinnitus and hardness of hearing, which gradually increased in severity, culminating in half an hour in nausea and vomiting, which were gradually followed by relief of all the symptoms. During these attacks of buzzing in the ear, the hearing was diminished, as could be shown by the watch and voice. But as the function was restored as the attack passed off, the idea naturally arises that the symptoms might have been due to spasm in muscular structures in the middle ear. It also leads to the conclusion that the term Ménière's disease, by which such attacks have generally been called heretofore, has been applied too widely, if by it disease only of the labyrinth or parts of it, has been meant. Aural vertigo should be the general term; Ménière's disease may be limited to the labyrinth. It is highly probable that hearing, varying quickly within short periods of time, could in no case be referred to alterations in the labyrinth, for the latter, as far as they have been demonstrated to exist, have been permanent changes, and not recurrent. Recurrence, however, is a well-known feature in muscular spasms.

Hearing Lower Tones better than Higher Ones.—In many instances which have come under my notice, I have been informed by the patients that they could hear some kinds of sounds very much better than others. Thus, in two cases the patients voluntarily said that they heard thunder (bass note) better than the chirping of crickets, or high tones on the piano. And, on being tested with watches, one patient said that he heard that watch better which gave the tick of a deeper note. Experimentally, I have shown[3] that a deep note has the advantage over the high ones in cases of increased labyrinthine pressure. In an increase of the pressure within the labyrinth, the stapes becomes more fixed, and it is at this point that the vibrations begin to grow less marked as the pressure in the labyrinth increases. In such a case it is manifest that if vibrations from without be normally conveyed to the stapes, they must there meet with hindrance as they endeavor to reach the labyrinth. Only the most powerful waves are able to overcome this obstacle, and to force the stapes to undergo a to-and-fro movement with the rest of the

[1] See Philadelphia Medical Times, Oct. 17, 1874.
[2] Questions of Aural Surgery, pp. 262–263.
[3] Archives of Ophthalmology and Otology, vol. ii.

chain of ossicles. I have, therefore, thought that it might be asked: Could not the inability to hear high notes, while low ones are heard almost normally, be construed into a sign that the stapes is impeded, either by undue pressure in the labyrinth, or by catarrhal fixation in the oval window? That the cause of such a peculiar alteration in hearing probably does not lie in an undue tension of the membrana tympani, appears from the well-known physical fact that the tense membrane is more sensitive or susceptible to vibrations of high notes than to those of low ones.

Do the position and extent of perforations in the membrana tympani cause variations in hearing-power for certain sounds? This question may be answered in the affirmative, according to the experiments of Wolf. He divides defects of the membrana tympani into five groups, viz., (1) small defects in the lower segment of the membrana tympani; (2) defects as large as a quadrant in the lower part of the membrana tympani; (3) defects as large as a quadrant or a quadrant and a half; (4) defects as large as three-quarters of the membrana tympani; and (5) complete defect of the membrana tympani and loss of the malleus and incus. Vowels are heard invariably better than consonants in all of these cases. I have observed that defects of the membrana flaccida are always attended with great hardness of hearing. This is probably due to an implication of the joints of the ossicles.

In testing hearing, we must consider the way in which the sound is conveyed to the ear, whether through the apparatus of the middle ear, or by the bones of the head. The latter, without doubt, has more influence than has generally been supposed.[1] It is really astonishing to discover the amount that one may hear with a normal ear stopped up. This shows how much sound may be conveyed to the auditory nerve through osseous tissue. A want of proper appreciation of this fact has led to great errors in testing hearing, in cases of one-sided deafness. Merely closing the good ear, and leaving the poorer one open, is not sufficient. The hearing must be tested, first, in the better ear when stopped up and turned towards the examiner, the worse ear being open. When the amount of hearing in the better one, made artificially deaf for sounds through the air, has been determined, then we may see what effect opening and closing the deafer ear has on the hearing of the stopped-up, better one. The result will be the amount of hearing for the worse ear.

A plan similar to the foregoing, and one which I have used for a long time, in cases of one-sided deafness, is the following: Place the patient so that the affected ear is towards the surgeon. Then stop, with the finger, the better ear, the ear not to be tested. This may be done by the patient or by an assistant; preferably by the latter where great certainty is desired. Then, with the affected ear open and turned towards the surgeon, let tests of its hearing-power be made. When the limit of hearing on that side is obtained, let the ear be closed as the other is, and then, with the ear still turned towards the examiner, let tests be made again. If the closure of the deaf ear, the one turned towards the surgeon, cause no difference in the hearing-distance already obtained, it is fair to conclude that whatever amount of hearing exists is not due to a passage of sound through the external auditory canal of the ear turned towards the surgeon. In such a case the conclusion must be that either sound goes more easily through the bones of the head on the

[1] See important papers by Dennert and Lucæ, Archiv f. Ohrenheilk., Bd. x.

affected side than through the meatus to the auditory nerve, which would be absurd, or that sound has reached the brain by the other ear, and that the affected ear is totally deaf. If, however, stopping the ear turned towards the examiner—the ear supposed to be the deafer—make that ear still deafer, let the examiner approach the patient and repeat the tests till they are heard once more. The second hearing of them is evidently due to conduction of sound through all obstacles represented by cranial bones and the finger in the meatus, and must not be regarded as aerial conduction. The extent of the power of the ear to hear by aerial conduction will be expressed in the difference between the limit of the first test and the limit of the second. Thus a patient may hear speech as far off as eight feet, with the good ear stopped and turned away, and the affected ear open. When the latter is stopped, speech is no longer heard at eight feet, but it may be perceived by the patient at a distance of three feet, both ears still being kept firmly stopped. In such a case, not the former distance, but the difference between it and the latter distance, viz., *five feet*, must be considered the amount of aerial conduction by the external auditory canal, for that represents the *amount* of loss of hearing caused by stopping the meatus.

Wolf's Word-Tests.—In testing the power of an ear to hear the human voice, it seems to me that we gain some very practical hints from Wolf's system of word-tests. Wolf, in his very valuable work, has divided defective drum-heads into five groups (vide supra, p. 971), and in each of these he has applied a certain list of chosen words as tests. At the end of his observation of the hearing in each group, he has struck an average of the words heard, and has thus, as it seems to me, made a practical suggestion. Printed slips with words containing the different vowels and consonants at the beginning, middle, and end, might easily be arranged in all languages, and the aurist provided with them could always discover the ability of his patient to hear given vocal sounds. The average of the patient's misses and successes would give his hearing power.

A Conventional Sound-Unit.—A conventional sound-unit might be constructed so as to be of uniform and invariable intensity, but "intensity of sound-sensation and intensity of sound-producing vibration are two entirely different things. The first is a physiological phenomenon, and varies with individuals like all such phenomena, and the second is a dynamical phenomenon. To assert that the first is proportional to the second, as all authors do, is to use *à priori* physics in which I have no faith."[1] Hence if such a sound-unit were made, it would possess only a limited value. It would also be open to the same objections as the watch, or the solitary note of any other test. One sound can no more become the test of hearing than one object can be the test of vision. Even speech itself, which affords the most convenient as well as the most ample test, will not fulfill all its capabilities unless it be studiously varied so as to bring into play all its elements, with their varied phonetic characters and intensities.

Kessel has laid down four conditions which any form of acoumeter should fulfill in order to satisfy the wants of the aurist of the present day: (1) The acoumeter must embrace a large range of tones in the most carefully graduated series; (2) The strength of the tones must be always the same; (3) The acoumeter must be able to test the hearing in one ear at a time, both respecting air and bone conduction; (4) The intensity of

[1] Prof. A. M. Mayer; Correspondence with the writer.

the notes must correspond as nearly as possible with that of the voice. Kessel has had an apparatus made which corresponds in the main with the above conditions. The tones are produced by means of metal teeth, which are set in vibration by keys placed in a brass cylinder, like those of an ordinary music-box. The teeth give the notes of the scale of "C major," throughout seven octaves, and, if desired, can produce even eight octaves. Discordant sounds may be produced by striking the notes of several octaves at the same time. The cylinder is turned by a handle, to which is fastened a pointer which indicates on a dial the pitch of the note given out. The air conduction is effected by means of a rubber tube, connected with the cavity of the apparatus. The latter is covered with poor conductors of sounds, and packed in a case, so that the sounds produced in the apparatus are inaudible even at a short distance from it, except through the gum tube. Bone conduction is effected by bringing the mastoid process into connection with a metal prong or bar, passing from the back of the comb-like piece containing the teeth heretofore alluded to.

Since by this means the air in the external auditory canal is alternately rarefied and condensed, and thereby the tension of the membrana tympani and the pressure in the labyrinth altered, we have a means of finding out under which of these conditions the hearing is best. The apparatus also shows that when both ears are unequally excited by the same sound, the latter is referred to the more stimulated ear, independently of direction. Thus if the right ear be brought near enough to the case to hear the sounds through the packing, and if then the rubber tube be brought around to the left ear, the observer will think the sound comes only from the left.

I have never had any experience with the apparatus devised by Dr. Kessel, but it seems fair to assume, from what is known of the character of the voice in speaking as a test, that the instrument alluded to provides the aurist with no better means of testing than he always possesses in the use of speech.

There are needed, in any form of test, comprehensibleness, scope, delicacy, gradations without great intervals, convenience of application, inexpensiveness, and invariability. The watch and tuning-fork have been described, and conclusions drawn respecting them. The further the investigations have been carried, the more conclusive have appeared the reasons for assuming that the voice will render most aid in determining the state of the hearing. Nothing is more convincing of this than the fact that all artificial means, yet proposed, have been modelled more or less after the voice, or some of the component sounds of speech.

Invariability would always be an argument in favor of any form of test, and it has been urged in behalf of the watch, the tuning-fork, and other forms of artificial test-means. This certainly is desirable for comparisons during treatment, no matter what form of test be used. But every aurist can learn to modulate his voice so as to be able to command always the same degree of loudness or lowness in making tests with it. Even if artificial means were as superior to the voice in invariability as some have thought, the far greater range of the latter as a musical apparatus especially adapted to the ear, would place it far ahead in the list of tests for hearing.

THE FUNCTION AND UTILITY OF THE ARTIFICIAL DRUM-MEMBRANE.

BY

H. N. SPENCER, M.D.,

OF ST. LOUIS.

I SHALL present a resumé of this subject, as far as it has been possible, in a limited time and with the literature at my command, to obtain it, and in addition I am happy in being able to submit so much of the *present* status of the subject among aurists at home and abroad, as will be my privilege.

With the desire to present something practical on a subject of such practical importance as this, and which would carry authority with it, I early addressed letters to as many of those who are engaged in this special field as my time allowed, submitting questions which appeared to me to cover every point, so that if possible I might be able from these advanced sources to obtain the material which would admit of a crystallization into truth.

It would be desirable to know accurately the condition of the ear which indicates the employment of an artificial drum-membrane, the contra-indications, and the best form of membrane under varying circumstances. It should not be a matter of taste, like the preference of one prospect or one piece of music to another. As scientists, we should, as far as possible, have fixed laws to govern us; yet, dealing with forces which themselves vary, we recognize that this exactness is not always to be attained.

It appears that Marcus Banzer, in 1640, first suggested the use of the artificial membrane, not with the view of improving the hearing, but as a protection to the cavity of the tympanum in cases where it was exposed from loss of the normal membrane by ulceration. The construction of his apparatus was exceedingly rude, consisting of a tube cut out of the hoof of the elk, with a bit of pig's bladder to represent the membrane covering its proximal or inserted end. This was to be introduced to half the depth of the meatus. There are allusions to this apparatus, or to similar contrivances for the same purpose, in the writings of Leschevin, 1763, Autenreith, 1815, and Lincke, 1840. The appliance of Autenreith, a description of which he published in the *Tübinger Blättern für Naturwissenschaft und Arzneikunde*,[1] consisted of a short tube of lead, very thin and elliptical-shaped, the inner end of which was covered by a membrane made of the air-bladder of a fish, which was put on wet and varnished after it became dry. Lincke describes his apparatus in his treatise on diseases of the ear;[2] it is substantially the same as that of Autenreith. In 1842, Yearsley accidentally discovered an altogether new use of the artificial drum-membrane, viz., as a means of improving the hearing. I quote from a paper published in the "The Lancet" (July, 1848),[3] entitled "On Deafness."

[1] B. i. H. 2, S. 129. [2] Handbuch der Ohrenheilkunde, 1845, B. ii. S. 446.
[3] Vide Allen, "On Aural Catarrh and Curable Deafness," 2d edition, 1874, p. 366.

Up to the present time, no successful mode of treating perforations of the membrane of the drum, or the relief of the accompanying deafness, has been discovered by the profession at large. The only means resorted to has been the removal of pus or mucus from the tympanal cavity by syringing, or rendering it free by passing air through the perforation, by way of the Eustachian tube. Either of these proceedings will produce a temporary improvement of the hearing in cases where the tympanum suffers from obstruction, but in many others, when such a state does not obtain, they are of little if of any service. I have, however, the extreme gratification of promulgating a mode of relief for deafness attended by loss of the membrana tympani, which will cause great surprise among the readers of The Lancet, not less from its extreme simplicity than from the extraordinary success which generally attends its employment. In 1841, a gentleman came from New York to consult me under the following circumstances: He had been deaf from an early age, and, on examination, I found great disorganization of the drum of each ear. On my remarking this to him, he replied, "How is it, then, that by the most simple means I can produce in the left ear a degree of hearing quite sufficient for all ordinary purposes? in fact, so satisfied am I with the improved hearing which I can myself produce, that I only desire your assistance on behalf of the other ear." Struck by this remark, I again made a careful examination of each ear, and, observing their respective conditions, I begged him to show me what he did to that ear which I should have unhesitatingly pronounced beyond the reach of remedial art. I was at once initiated into the mystery, which consisted in the insertion of a spill of paper, previously moistened at its extremity with saliva, which he introduced to the bottom of the passage; the effect of which, he said, was "to open the ear to a great increase of hearing." This improvement would sometimes continue an hour, a day, or even a week, without requiring a repetition of the manipulation.

Dr. Yearsley seized upon the idea which this case presented, and gave to the profession an artificial drum-membrane which is known as "Yearsley's cotton-wool," consisting of a small pellet of moistened cotton-wool which is inserted to the bottom of the external auditory canal. Without detracting from the rude attempts which had preceded this, and without claiming for Yearsley that he had made a discovery, strictly so called, of anything previously altogether unknown, yet it is due to him and to ourselves, since discovery is a relative word, to credit him with being practically a discoverer, for bringing to our knowledge and for giving to the world this new *use* of a contrivance of which we otherwise might have remained in ignorance until now. In 1853, eleven years later, Toynbee gave to the profession another form of artificial membrane, which he described in his "Treatise on Diseases of the Ear," and which was composed of a vulcanized India-rubber disk (the thinnest layer of it that was procurable), through which was passed a silver wire, fastened in the centre by means of two very fine plates of silver, having a diameter of about three-quarters of a line. "The silver wire is of sufficient length to admit of the membrane being introduced or withdrawn by the patient, but is not perceivable externally except by special observation." I shall have to notice hereafter other forms of artificial drum-membrane, which, while deserving a special mention, are not properly referred to in this connection.

It will be interesting now to consider the conditions of the ear which admit of the use of the artificial membrane, and this will be profitably studied by passing in review the theories and practical thoughts, on this subject, of explorers in otology, from the period of Yearsley down to the present time, augmented by views which are entertained by men of to-

day. To preface this step: It is not deemed necessary to refer to the function of hearing, further than to state in general terms that the conducting media involved are the membrana tympani, the machinery of the cavity, and the membranes of the oval and round windows of the inner wall of the tympanum. Like the media through which vision is effected, there is so nice an adjustment of these forces that to have one affected injuriously, influences the efficiency of each of the others, and of the whole machinery. This need not to be demonstrated. It will be understood, then, that, in considering what are the conditions of the ear admitting of the use of the artificial membrane, we have not only to take into consideration the membrana tympani and its functions, but what are the functions of the tympanic cavity, etc., which are influenced by every deviation from the normal condition of the membrane, and *vice versâ*. The artificial membrane is designed to supply some force that is wanting, or that operates inefficiently, and this inoperative condition of the conducting apparatus which can be thus measurably remedied, may be due to a variety of causes, such as solutions of continuity of the membrana tympani; changes in the lining membrane of the tympanum, associated with perforation of the membrane; loss of power in the tension-muscles of the cavity, with partial or entire destruction of the membrane; loss of two of the ossicles, the membrana tympani being gone, the stapes *in situ;* flaccidity of the membrane; solution of continuity in the articulation of the ossicles. It may be considered, then, that it is the design to show in what follows the rationale of the functional gain by the artificial membrana tympani in these conditions, which I have enumerated in the order of their frequency of occurrence.

Toynbee reasoned that the artificial membrane "confined the vibrations to the tympanic cavity, and concentrated them upon the labyrinth." This conclusion he founded upon experiments which proved to him that the guttural orifice of the Eustachian tube was closed "except during the momentary action of certain muscles," which made the tympanum a shut cavity for all purposes relating to the passage of sonorous undulations, and next upon the experiment with the tuning-fork, which showed that the sonorous vibrations communicated to the bones of the head appeared much louder when the meatus externus was closed than when the orifice was open. This led to the conclusion that the sonorous vibrations imparted to the cavity of the tympanum, could only make their due impression on the membranes of the labyrinth when strictly confined to the tympanic cavity, and Toynbee's artificial membrane was designed to supply this, which he considered was the office of the normal membrane.

And in directing its application, he says: "As will be imagined, great care must be taken to cut the membrane so that it shall fit the inner extremity of the meatus with exactness; since if too large it would cause discomfort, and if too small it would not fulfil its purpose of rendering the tympanum an air tight cavity. It is not easy, in all cases, to fit the artificial membrane so as not to allow of any communication between the air in the tympanum and that in the external meatus; this however is the object which should always be aimed it." This view of Toynbee's did not obtain for any length of time, as practical experience with the use of the artificial membrane soon showed that, to effect the improvement in the hearing, it did not require that the perforation should be closed; and this should have been apparent earlier when we consider that Yearsley's artificial membrane of cotton-wool preceded Toynbee's rubber disk, and the increase of hearing effected by it could not be accounted

for by Toynbee's mode of reasoning. As far as I know, Erhard and Von Tröltsch were the first who suggested that the effect of this mechanical aid to hearing did not depend upon its rendering the tympanum a closed cavity, nor upon its affording a surface for the reception of sound, nor upon its furnishing a conducting medium, but that it acted by virtue of its pressure upon the stapes. This was first concluded when it was discovered that in this position the greatest amount of improvement was effected, and no philosophical explanation was essayed. It is but doing Toynbee justice to add that his views subsequently underwent considerable modification, as will appear from a statement of the conditions of the ear in which the artificial membrane will be found most efficient, given in the supplement to the edition of his work, edited by Mr. James Hinton,[1] and which he was partly led to adopt, it is stated, by intercourse with Dr. Julius Erhard, "who, without any perforation, found his hearing much improved by the use of cotton-wool, and published his experience in a paper entitled 'Deafness Curable by Pressure.'" These conditions are as follows:—

(1) Disconnection of the incus and stapes, the membrana tympani being entire, but the tensor tympani ligament, or the mucous membrane of the tympanum, being relaxed. (2) Partial or complete absence of the long process of the incus, the membrana tympani being entire. (3) Disconnection of the stapes and incus, the membrana tympani being perforated, and the tensor ligament or the mucous membrane of the tympanum being relaxed. (4) Partial or complete loss of the long process of the incus, the membrana tympani being perforated, and the ligaments of the stapes being relaxed.

Erhard[2] says:—The improvement in the hearing is appreciated at the moment that the surface of the artificial membrane which is being introduced comes in contact with the surface of that which was formerly the conducting apparatus, restoring the continuity which has been destroyed.

Von Tröltsch[3] says:—It is not yet determined definitely in which way the artificial membrane produces its often astonishing effect. Various explanations of its mode of operation are in favor. According to Lucæ, it is the increased pressure which is exercised upon the labyrinth-fluid, which is of outweighing importance to everything else. Politzer refers the improvement in the hearing to the removal of the irregular nodes (*Schwingungsknoten*) which are produced in every perforated membrane—and also to the rubber disk acting like the true vibratory membrane, and serving to convey a considerable number of vibrations to the ossicula. In the least number of cases is the increased hearing to be referred to the closure of the cavity, which was Toynbee's theory. In many instances we observe marked improvement where the rubber disk does not effect closure of the opening in the membrana tympani. . . . . That the closure of the opening is not essential, and not the true explanation in solution of this enigmatical question, I was able to see in a case that presented itself to me where I could close a very small opening in the membrane with collodion, or a thick solution of gum, without producing the least effect upon the hearing; whereas a very marked and immediate improvement resulted from the introduction of the rubber disk, or of any other foreign body, so that it would press upon the membrane. This pressure upon the membrane, or upon the manubrium mallei, seems in most cases to be essential to effect the desired result.

Politzer, in a very interesting *brochure*, entitled "Ueber das künstliche Trommelfell und seine neueren Modifikationen," which first appeared as an

[1] 1868. p. 452. [2] Krankheiten des Ohres, 1875, S. 230.
[3] Lehrbuch der Ohrenheilkunde. Fünfte Auflage, 1873, S. 400.

article in the *Wiener Medizinal-Halle*, 1864, after a statement of the views of Toynbee, says:—Although the phenomena upon which he founds his explanation present themselves to every practical physician as correct observations, on the other hand, it must be allowed that they cannot altogether clear up the question of mode of action of the artificial membrane. Opposing views to those of Toynbee have been urged by other authors (V. Tröltsch, Erhard), and are in more general favor at the present time. It may be stated positively that the view entertained by the latter author, *i. e.*, that the artificial membrane operates principally through pressure upon the remnant of the membrane and the chain of bones, is the true explanation in the majority of cases; this is more evident when we regard the pathological changes which occur in the tympanum as a result of the catarrhal process, and which have been more fully appreciated since Toynbee made his observations upon this subject. If a post-mortem examination be made of a person who has suffered from a suppurative, middle-ear catarrh, with perforation of the membrane, there will be found in many cases that the ossicles are fixed through adhesions, or are enveloped in adventitious tissue-formation. In other cases the ossicles have become so loosened in their articulations from the inflammatory process, that the slightest touch with an instrument causes them to fall apart. It is evident that in such a looseness of the articulations of the chain of bones, the sound-conduction would be interfered with in greater or less degree; especially would this be the case if there were complete separation, for instance, in the incudo-stapedial articulation. In a case of this kind, now, the artificial membrane would operate to improve the hearing through pressure, by restoring continuity in the chain of bones and aiding sound-conduction.

The above-cited observations of Toynbee, upon which he rests his theory of the mode of action of the artificial membrane, permit of another solution to this question. If the membrana tympani is perforated, the deafness which follows depends, *first*, upon the hole in the membrane by which the surface for the reception of sound-waves is diminished, and consequently a less number of sound-waves are conveyed to the chain of bones: particularly is this the case if the destruction of the membrane is in the neighborhood of the manubrium mallei; *second*, upon change in the conditions surrounding the ossicles, as by accumulation of secretion, or by loosening or fixation of their articulations. Upon the latter changes depends the degree of deafness, as experience proves that in large perforations, where no considerable change has occurred in the condition of the chain of bones, there is, of course, a diminution in the hearing, but yet the hearing will still often be sufficient for ordinary purposes, and the deafness never is in degree proportional to the extent of the defect in the membrane. This phenomenon, which is so striking, has its explanation in this, that in the large perforation, the sound-waves, without being received and conducted by the remnant of membrane, and malleus and incus, fall direct and full upon the foot-plate of the stapes and the membrane of the round window, and so reach the labyrinth in considerable numbers. The improvement in the hearing, in cases where the perforation is not extensive, which is effected through the closure of the opening by means of a drop of fluid, has its explanation in this fact, that, the continuity in the membrane being restored, the irregular nodes are removed which exist in every case where there is an opening existing in the membrane.

Moos[1] says:—According to the observations of Lucæ, Politzer, and myself, it has been proven that, by the application of the artificial membrane, the intra-auricular pressure is increased. There is at the same time this advantage, that in some cases in which the ossicles are still preserved, but are loose in their articulation, which has resulted from an active, purulent inflammation of the middle ear, the artificial membrane, by pressure, restores them to a proper condition for the conduction of sound-waves.

[1] Ohrenkrankheiten, 1866, S. 275.

Dalby[1] says:—The increased hearing may therefore be said to be produced by approximating the articulations of the ossicles, or supplying their place when these bones are partially wanting; which Dalby further states was in substance the explanation offered by Dr. Yearsley.

Roosa[2] says:—The improvement to the hearing is probably due to the restoration of the interrupted continuity of the ossicula auditus to the fenestra ovalis and the labyrinth.

Hinton[3] says:—The question whether the artificial membrane operates by closing the orifice in the membrana tympani, or by supporting the ossicula and especially the stapes, is now decided in favor of the latter view.

Allen[4] says:—The benefit is derived from support being given to the ossicula, by which they are enabled to exercise that due pressure at the fenestra ovalis which keeps the membrane of the fenestra rotunda in a condition susceptible of vibrations, and capable of transmitting them to the nerve expansion in the labyrinth.

In response to inquiry, I have obtained, relative to this question of conditions of the ear and function of the artificial membrane, these further very interesting views. (I would state that I did not submit these questions to many whose views would be highly esteemed, for reasons which have already been assigned, and regret it as detracting from the value and interest of this report. Three to whom the questions were submitted, made no reply.)

Dr. Clarence J. Blake, of Boston, summarizes the conditions of the ear in which the artificial membrane may be used, thus:—(1) Solution of continuity of the membrana tympani, in which the artificial membrana tympani restores a surface for the reception of the sound-waves, or, by closing a small opening, prevents the simultaneous impact of the sound-waves upon the base of the stapes and the remaining portion of the membrane, a condition which is shown by experiments to result in interference;[5] (2) Thickening of the mucous membrane of the tympanic cavity, associated with perforation of the membrana tympani, the increased pressure given by the artificial membrane resulting in the readier conduction of short sound-waves; (3) Destruction of the membrana tympani, the artificial membrana tympani receiving the sound-waves on its outer surface, and conveying them directly by contact to the incus or stapes; (4) Loss of the incus in suppurative otitis media, the artificial membrane being made to press directly upon the stapes, thereby restoring the degree of tension of the membrane of the fenestra ovalis. ("I have seen in Politzer's clinic good results in such a case from the pressure induced by a small cube of rubber-elastic, one millimetre in diameter, resting upon the stapes and extending across the tympanic cavity.")

Dr. D. B. St. John Roosa, of New York, states that, according to his experience, the artificial membrana tympani may be used where there is a partial or complete loss of the natural membrana tympani, with a moderate amount of suppuration, or no suppuration at all, and with one or more of the ossicles *in situ*. If there be much suppuration, the irritation of a foreign body, such as an artificial drum-head, will always be apt to increase it. In a few rare cases it is useful, where the natural membrane is entire but very much thinned by atrophy. Its use should be limited to those cases where with the above conditions there is a great impairment of hearing, *i.e.*, inability to hear ordinary conversation. . . . The improvement in hearing is effected primarily by pres-

sure upon the stapes, re-establishing the proper relations of that bone to the fenestra ovalis, vestibule, and cochlea.

Dr. O. D. Pomeroy, of New York, says:—Any condition in which the base of the stapes fails to exert the requisite pressure upon the oval window, and consequently upon the waters of the labyrinth. The lesions resulting in this condition are: (1) Perforation or loss of membrane; (2) Flaccidity of the membrane, either due to a cicatrix or to other causes whereby the membrane fails to close down firmly upon the ossicles; (3) Loss of one or two of the ossicles, the stapes being *in situ;* (4) Separation from any cause of the ossicles from each other; (5) Partial luxation of the base of the stapes, or great relaxation of its annular ligament. The discharge from the ear must be moderate in quantity or absent. Polypi or granulations should be removed or destroyed. The ear must bear the pressure of the membrane without the production of either pain, tinnitus, vertigo, nausea, etc., increased discharge, or irritation of the chorda tympani.

Dr. Arthur Mathewson, of Brooklyn, says:—Like the natural membrana tympani, the artificial serves to concentrate the force of the sound-waves through the ossicles on the nervous apparatus of the inner ear, focalizing these waves, as it were, as rays of light are brought to a focus on the retina by the refracting apparatus of the eye. In cases in which there is stiffening or anchylosis of the joints of the ossicles, so that they cannot transmit the sound-waves, the artificial membrane only impairs the hearing.

Dr. Albert H. Buck, of New York, says:—As I comprehend the matter, the artificial drum-membrane serves to intensify the sound-impulses. In the case of Hassenstein's membrane, I can readily understand how the vibration communicated to such a solid body, projecting as it does beyond the orifice of the meatus, may be transmitted to the hammer, and so on to the labyrinth, with a greater force or intensity than would have been the case had the same waves of sound reached the auditory nerve without the intermediation of such a solid body—the larger solid body offering a greater surface to the waves of sound than does the hammer which is a smaller body. If there is a condition of anchylosis, an entire membrana tympani would, it seems to me, be a much less efficient intensifier of sound-impulses than would Hassenstein's contrivance. Hence, where there is anchylosis, it is quite possible that the total absence of the membrana tympani may be rather a benefit than otherwise; for, in its absence, the sound-impulses can strike directly against the foot-plate of the stirrup (in other words, upon the fluid of the labyrinth) with greater force than they could *viâ* the chain of ossicles, the membrana tympani being intact. The temporary benefit of artificial perforation, in such cases (of anchylosis with entire membrane), may be explained in accordance with this view.

Dr. C. H. Burnett, of Philadelphia, in reply to the question "What is the office of the artificial membrane; how is the improvement effected?" says:—This question is one not only of intense interest, but of the greatest importance, for upon its answer depends, as it seems to me, the gist of the entire subject of application and usefulness of the false drum-head. Its office is emphatically to restore the proper isolation of the ossicles of hearing. These will not perform their normal functions if they are too tightly locked, or if they are too loosely connected. Hence, in some cases, the false drum-head would have to be adjusted so as to gently overcome the indrawing of the malleus by the tensor tympani, while in other instances the benefit derived from the false drum-head would be entirely due to pressure inward, since it would thus overcome a too great relaxation of the joints of the ossicles, and thus enable them to swing with each delicate wave of sound. The latter is more easily accomplished, and perhaps is the more usual demand made on the false drum-head. But, now and then, the more the false drum-head is made to press on the remnants of the sound-conducting parts, the less the patient hears. In the cases of this kind which I have seen, the membrana tympani has been largely destroyed, but the ossicles have been present, and their attach-

ments normal, especially that of the tensor tympani to the malleus. Manifestly, here the bones have been already too much drawn inward, and pressing down a pellet of cotton would but increase the defective isolation. If, however, in such cases the artificial membrana tympani be placed so as to gently overcome the indrawing of the malleus, the entire chain of ossicles may be freed, and allowed once more to swing normally. This I have successfully done by tucking the upper edge of the round or flattened pellet of cotton *behind* the manubrium, *not in front of it.* The latter would be only an additional inward force, but the former adds *outward* force just enough to overcome the retraction of the malleus. The base of such a false drum-head should rest as nearly as possible along the line of insertion of the lower half of the membrana tympani. In doing this, should some of the lower portion of the artificial membrane extend into the tympanum, as it almost surely will when the membrana tympani is largely destroyed at its lower border, no harm comes of it, if there be no discharge from the ear when the artificial drum-membrane is inserted, and if the ear be examined by a competent person from time to time in order to learn the condition of the parts where the cotton pellet lies. The great objects to be gained in such cases of undue retraction of the malleus, and consequently of the entire chain of ossicles, are: (1) a good support for the base of the false membrana tympani; and (2) the adjustment of its upper edge *behind* the lower end of the manubrium. Of course, large perforations involving the lower half of the membrana tympani are supposed in what has just been said. A small perforation does not as a rule cause as much deafness as a large one, and in any event the artificial membrane used in the former is to be laid over the perforation.

Prof. Schwartze, of Halle, says:—The indication for employment of the artificial membrane exists only in a partial or total defect of the membrana tympani, and it is contra-indicated by a subacute inflammation, or a profuse otorrhœa.

Prof. A. Lucæ, of Berlin, writes:—The artificial membrane should not be employed, and is of no value, in ancient perforations where the suppuration has ceased, and where the edges of the perforation have cicatrized.

Prof. Politzer, in his communication to me, says:—It is important for the action of the artificial membrane, as well the rubber disk as the pellet of cotton, that it should be fastened on a solid or elastic stem, by which a certain pressure is exercised upon the deeper parts. The rubber disk or the cotton pellet which is fastened on a *thread*, will not produce so marked an effect, because this pressure from without is not then exerted.

Prof. Weber-Liel,[1] in a preliminary communication, states that according to his researches the band connecting the foot plate of the stapes with the edge of the oval fenestra, described heretofore as the "ligamentum orbiculare baseos stapedis vestibulare," should be considered rather as a circular membrane. It is true that it appears on ordinary examination only as a very narrow band, yet well prepared microscopic specimens, more than physical experiment on fresh preparations, demonstrate that we have to deal with a *relatively broad, independently vibrating, membranous band.* On account of the peculiar position and mode of union of the stapes with the edge of the oval window (the membrane generally going abruptly down to the edge of the stapes looking toward the tympanum), it is only under certain conditions that we obtain a demonstrative view. In well-prepared specimens, where the covering mucous membrane of the tympanum has been previously removed, well-defined, radiating fibres can be observed in the circular membrane. The elastic-fibre layer of Rüdinger, between the so-called "ligamentum orbiculare baseos stapedis vestibulare" and the "ligamentum baseos stapedis tympanicum," constitutes the real, very elastic attachment of the stapes-plate in the foramen ovale. In illustration, there was presented, with this communication, a preparation of the

[1] Verhandlungen der physiologischen Gessellschaft zu Berlin. 3 Juni, 1876.

human ear in which the wall of the vestibule opposite to the oval window had been opened, the edge of the opening having been filed and widened to admit a thin glass, which was made to close the opening hermetically, and through which the circular membrane could be closely observed, enlarged 15–40 times. In the external auditory canal there was loosely placed a glass tube, to which was attached a piece of India-rubber tubing, through which sound-waves could be introduced. At once, very low speaking, or singing high and low tones, into the tube, produced plainly visible excursions of the light reflexes on the circular membrane, but none whatever on the stapes-plate. The light reflex excursions were very marked with stronger and lower sounds, but only very loud singing into the tube produced the light reflex excursions on the stapes itself. The tensor tympani and stapedius muscles appeared to effect the changes of tension in the circular membrane. It was shown how, by pulling on the stapedius muscle, the vibrating faculty of the circular membrane was at certain points reduced or entirely checked. The counter-pressure of the labyrinth-fluid was replaced in the preparation by air, which could be compressed by means of a rubber balloon through a glass tube introduced into the closed vestibule, a piece of rubber tubing connecting the distal end with the air bag.

I am indebted to this author for a personal communication, in which he applies this newly discovered anatomical relation to the question we are considering: "The stapes, regulating the intra-labyrinthine pressure, exercises also an influence upon the circular membrane through the operation of the sound-waves and the tensor tympani and stapedius muscles. If the normal tension of the membrana tympani and chain of bones and muscles be impaired, in consequence of defect in the membrana tympani, it is perhaps the pressure which is exercised by the artificial membrane on the stapes to which the improvement in the hearing can be referred. The intra-labyrinthine pressure and the tension of the circular membrane may by this means be brought nearer to a normal condition." In connection with this interesting statement of Prof. Weber-Liel's, I may refer to the experiments performed by Mach and Kessel,[1] conducted with a view to determining "whether a traction upon the muscles of the tympanum will produce an alteration in the consonance of the auditory apparatus for notes of various pitch," and as a result of which they state, "our conclusions are in unison with those of former investigators. All observers agree that contraction of the tensor tympani, whether produced artificially or by natural causes, will render high notes more audible than low ones." This phenomenon has presented itself, I do not doubt, very many times to every gentleman present, in the course of treatment of suppurative and non-suppurative inflammations of the tympanum, there being at periods a marked improvement in the hearing of high tones, with no increase, or a positive decrease, in the hearing of low tones.

We may now consider the contra-indicating conditions to the use of the artificial membrane. After what has gone before, I shall consider that a mere statement here will be sufficient, and will not be controverted by any. In brief, then, the contra-indications to the employment of the artificial membrane are found (1) in a profuse suppuration; (2) in the presence of any adventitious growth in the tympanum or external auditory canal; (3) in acute disease; (4) where there is pain, or where there are cerebral symptoms; (5) where the artificial membrane has been tried and found to produce irritation; and (6) in all cases where there does not exist a degree of intelligence sufficient for the self-introduction and

[1] Versuche über Accommodation des Ohres; Sitzb. der k. k. Akad. der Wiss., 1872.

removal of the artificial membrane, or for the formation of a judgment as to the indications for its continuance or discontinuance, and in cases of young children.

The *forms of membrane*, and I shall enumerate only those which have met with some favor, and are in use among aurists to-day, are as follows:—(1) Yearsley's cotton-wool. (2) Toynbee's[1] rubber disk. (3) Hassenstein's (of Gotha) modification of Yearsley's membrane, made by attaching it to a pincette for its easier introduction and removal, and in order to supply an increased pressure. (4) Lucæ's modification of Toynbee's membrane; consisting in the removal of the metallic button and wire, and in the substitution of a fine rubber tube attached by a solution of gum to the outer surface of the disk; the tube serves for its introduction by means of a probe. (5) Politzer's artificial membrane, which is cut out of the wall of a heavy India-rubber tube; it is from four to five lines long, and should be one and a half or two lines thick; the upper end, through which the wire of Toynbee's membrane is passed, is somewhat broader than the lower. It is recommended in charity practice, for the readiness with which it is made, and its comparative cheapness of cost. Politzer has further modified Toynbee's artificial membrane by fastening to the disk an artificial stirrup, to be used in cases where the head, neck, and crura of the stapes have been destroyed, and only the foot-plate remains in the oval window. The foot-plate must be susceptible of its normal movements. (6) Gruber overcame the danger which is liable to occur in the use of Toynbee's membrane, of the disk becoming separated from the stem and being left behind in its attempted removal, by attaching a thread to the disk, and also to the ring which is formed in the outer end of the wire, for its extrication in the event of such an accident. (7) Hartmann[2] has proposed an artificial membrane, to be made of whalebone, six to seven centimetres long and one to two millimetres broad, and as thin as possible. It is doubled upon itself to form a loop, after it has been wrapped with cotton. It is recommended for the elasticity of the pressure which it makes, for its easy introduction and removal, and as a means of treating the cavity.[3] (8) Blake[4] recommends the use of a disk of writing paper, to be employed only in a certain class of cases; at the same time that it improves the hearing, the disk has its chief value in its office as a therapeutic agent.

The conditions of the ear presenting the indications for the employment of the artificial membrane, which have been stated at such length, occupying the greater part of the time allotted to this paper, with the anatomical peculiarities of the location, constitute the argument upon which is based the preference for Yearsley's cotton-wool. Of all the forms of membrane which may be committed into the hands of the patient—and it should be kept in mind that this is its fate—this form, in my experience, has proved to be the simplest of introduction, the easiest of adaptation in the cavity, and much the least likely to produce irritation—which latter must be the constant fear of every intelligent wearer of such a contrivance. In its employment, it will not be forgotten that the artificial membrane (of whatever form) is a foreign body; and that, in those cases in which it will produce the greatest amount of improvement in the hearing, it will be liable to defeat what

[1] For description, see page 975.
[2] Archiv für Ohrenheilkunde, Band xi., Heft. 2.
[3] See page 985.
[4] See page 985.

should be our first concern, the arrest of a process which endangers the health of an individual, if not his existence, and compared to which the improvement in the hearing is a matter of very secondary importance. The high degree of deafness which so frequently obtains in chronic non-suppurative inflammation of the middle ear, is comparatively of rare occurrence, associated with suppuration in the cavity; and where it exists, we are apt to find more or less extensive destruction of the tympanal machinery, with the destructive process continuing. These are the cases which when first presented necessarily excite some apprehension in our minds, and which require a guarded prognosis. They are cases concerning which I have been led by sad experience to feel an unusual solicitude; and when after a patient care of months, it may be, such an ear has been recovered from this state of danger to a comparatively healthy condition, it is a question for the surgeon to decide, "Have I a right to hazard this result?" When the continued use of this mechanical aid to hearing has been determined upon—and circumstances at times will warrant such a decision—the question arises, What form of membrane shall I employ? And I care not what the degree of deafness, nor what the circumstances or condition of the patient making it desirable to have the functional relief, the conclusion cannot be influenced alone by the degree of improvement produced by this form of membrane or that, but the surgeon must also consider his responsibility in the case, and his duty to protect his patient, and he will put into his hands that engine which will be the least calculated to do him harm. If the rubber disk be used, it should be Lucæ's, and never Toynbee's with its metallic button.

I am further of the opinion that such a case should never pass entirely from under observation, but that the patient should report himself statedly for inspection to the aural surgeon. It is not without significance that some of those of enlarged experience and of honor among us, if they do not discountenance the use of the artificial membrane altogether, at least may be said to endorse its use, in any form, very qualifiedly. Among such are Lucæ and Schwartze, of Continental-European aurists, and Buck, J. Orne Green, Knapp, Mathewson, and Prout, of those in our own country.

Lucæ says:—It is well known that in a continuing, chronic suppuration, the artificial membrane improves the hearing in a high degree; yet it irritates, and retards the cure of the otorrhœa, so that it would appear more rational to entirely abstain from its use, and principally to direct the attention to controlling the suppurative process. I have, therefore, in my practice, restricted myself in the use of this appliance to those very rare cases in which it effects a marked improvement in the hearing, without at the same time producing any irritation whatever.

Schwartze says:—As a general thing, I may state that, in my experience, the artificial membrane is only in rare cases to be used as a means of improving the hearing. In most instances, the improvement is not so considerable that the patient will bear the trouble and inconvenience which necessarily attend wearing it; and, continued for a little while, it is soon thrown away.

J. Orne Green says:—I must say that my experience with them is not brilliant; occasionally, in *very* rare cases, they have improved the hearing, but even in these they are often not well borne.

Knapp says:—My own experience with artificial drum-heads has been so unfavorable that I hardly ever try them again.

The functional value of the artificial membrane has been sufficiently considered; there remains something to be said of its therapeutical uses, and I incline to the opinion that this is its office of greatest usefulness. It serves, in the first place, to protect the inflamed cavity from the pernicious influences of an unkindly atmosphere, and from particles of dust and soot; and, introduced to the depth of the meatus, in more or less profuse suppuration, may absorb the vitiated secretion,[1] and act as a slight irritant, where there remains a small perforation in the membrane with a subsidence of the middle-ear trouble, to excite a further reproduction of membrane and thus close the cavity. In the second place, through this instrument, astringent solutions may be retained in application to the cavity, often with great advantage. It is proper, however, to state here a precaution which may save others from an embarrassment to which I have been subjected. The cotton-wool should be moistened merely, never saturated, with the solution; as the continuous presence in the cavity and meatus of so much fluid might lead to the development of a myringo-mycosis. Did time allow, I might report a number of cases so treated. Prof. Politzer, in a letter, suggests a different method of employing the cotton-wool with the medicated solution. I shall give it in the connection in which he states it, as the whole subject is of interest:

The most important modification, since the year 1864, is that of Dr. Hassenstein, of Gotha, who has contrived a pincette in which the cotton pellet is fastened. It possesses advantages over Toynbee's artificial membrane in that (1) its introduction is less disagreeable to the patient; (2) In speaking and chewing, there is less often that disagreeable noise in the ear which accompanies the use of Toynbee's membrane; (3) It does not produce so much irritation; (4) The cotton takes up the secretion of the cavity; (5) By means of the cotton, which has been saturated in a concentrated solution of sulphate of zinc, sugar of lead, nitrate of silver, or alum, and then dried, and moistened again when it is to be used, a medicament can at the same time be retained in contact with the diseased mucous membrane of the middle ear. . . . In the same manner Dr. Arthur Hartmann's artificial membrane might be employed.

Dr. Clarence J. Blake informs me:—Lately, in cases of small perforations of the membrana tympani, the middle-ear trouble having subsided, I have covered the perforation with a small disk of writing paper, moistened; the sizing of the paper is sufficient to secure its adherence, and in some cases it has remained for several weeks; the slight irritation caused by the paper favors closure of the perforation by cicatrization, and the paper is then removed by the natural growth of the dermoid coat of the membrana tympani. Dr. Blake kindly reports a case to illustrate the effect of this disk of writing paper, taken from the Massachusetts Charitable Eye and Ear Infirmary's Record, occurring in his service:—

Case 2024, Vol. V.—Perforation of right membrana tympani from old otitis media purulenta, discharge having ceased; hearing for voice diminished, sound of the voice being heard at six feet, but not understood readily on account of loss of softer consonant sounds. Perforation in anterior segment, a little more than two millimetres in diameter. Disk of common note paper moistened, and applied over the perforation. Voice heard plainly, and conversation understood at twelve feet (June 6, 1876).

[1] I have been in the habit of using, for making artificial membrane, a prepared cotton from which the vegetable oil has been extracted; this substance answers well for the purpose, and is also a better vehicle than ordinary cotton for conveying medicated solutions to the tympanum.

July 1, 1876. Paper still in position, but has moved (by natural process of repair) one millimetre backward and downward. Perforation diminished in size.

July 18. Paper having been moved from over perforation, is reapplied, with a repetition of the former favorable condition.

Finally, it is not easy to determine in what percentage of cases the artificial membrane will prove of practical advantage, until it shall have been tried in every case of perforation of the membrane, including cases of one-sided deafness. We are ready to infer that the relative proportion to the whole number of chronic suppurations would be exceedingly small, where its use would be continued as a means of improving the hearing. Of 261 cases of ear disease presented during the last six months, taken apart from clinical cases, as affording opportunity for more careful observation, 34 have been cases of chronic suppuration of the middle ear —the right ear being affected 11 times, the left ear 8, both ears 15. Counting out all excepting the 15 cases of double-sided suppuration, for reasons that will appear manifest, but five of these have presented the warrantable conditions for the employment of the artificial membrane, and only one has continued the use of the artificial membrane after being left with it for self-introduction.

Dr. Blake has placed me under further obligations to him by furnishing these statistics:—

The total number of cases of otitis media purulenta, treated at the Massachusetts Charitable Eye and Ear Infirmary from Jan. 1 to August 5, 1876, was 267, divided as follows: Males 187, females 80; Right ear 95, Left 90; both ears 82. In several of these cases, artificial drum-membranes were tested, no record being made. I append notes of cases in which there was special record.

Case 1928, Vol. V. Otitis media purulenta of both ears; destruction of membrana tympani, only a rim remaining; patient hears voice, except immediately, with difficulty; cotton applied in both cases with great improvement in hearing for voice.

Case 1982, Vol. V. Otitis media purulenta; hearing for voice much diminished; wall clock (60 feet) not heard at 6 feet. After introduction of cotton drum, hearing for voice improved; wall clock heard plainly at 20 feet; noises in the street, unnoticed before, became very annoying. After remaining in place with continued improvement in hearing for four days, drum removed to allow of treatment of granular condition of tympanic mucous membrane.

Case 208, Vol. VI. Destruction of left membrana tympani. Malleus drawn inward in contact with promontorium. Incudo-stapedial articulation visible. Voice understood with difficulty at 3 feet. Cotton drum introduced, being so moulded as to present a convex surface inward, pressing on the incudo-stapedial articulation, and a plane surface outward. Voice understood readily at 6 feet.

Conclusions.

I. Of the various forms of artificial drum-membrane in use, the cotton pellet is preferable, for its greater simplicity and easier introduction, for comparative safety in its employment, and for the greater uniformity of its effect.

II. It has an advantage over all other forms of artificial drum-membrane, in that, over and above the functional gain which may be derived from it, there may be added its value as a means of treating the tympanum; and this therapeutical use of the artificial membrane has a great future in otology.

III. The continued use of the artificial drum-membrane, as a means of improving the hearing, is indicated in rare conditions, which can only be determined by the aural surgeon.

DISCUSSION ON DR. SPENCER'S PAPER.

After the reading of the preceding paper, Dr. SAMUEL J. JONES, of Chicago, said:—In some cases I have found the rubber disk of considerable service, but latterly I have used the cotton pellet almost exclusively, occasionally anointing it with cosmoline. Even in some cases of active suppuration, if the secretion be carefully removed, the cotton drum-head may continue to be used with advantage. This remark applies especially to the cases of those who must continue to hear in order to attend to their daily work. Such cases, however, should remain under the observation of the surgeon.

Dr. CHARLES H. BURNETT, of Philadelphia, said:—I believe that putting the cotton behind the malleus, when the perforation is large, is a great deal better in some cases than pressing it on the malleus, for there are some cases of large perforation in the drum-head in which deafness is the result of retraction of the malleus. In such cases, the malleus being retracted, the rest of the bones are pulled in, and the trouble is only increased if the artificial membrane pushes the malleus inward.

Dr. SPENCER said:—I beg to thank Dr. Burnett for his suggestion; it may be the key to an explanation of the failure of the cotton pellet in some cases.

MODIFICATIONS OF THE METHODS OF TREATING CHRONIC NON-SUPPURATIVE INFLAMMATION OF THE EUSTACHIAN TUBE AND MIDDLE EAR.

BY

SAMUEL J. JONES, A.M., M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE CHICAGO MEDICAL COLLEGE.

The method of inflating the Eustachian tube and middle ear, introduced to the medical profession by Politzer, possesses so many advantages for that special purpose as to have been almost universally adopted in the treatment of obstruction of the tubes, and of disease of the middle ear. Experience, however, has shown that violence may be done by the injudicious use of so large a rubber bag as that advised by Politzer. More especially is this likely to occur when only one of the Eustachian tubes is affected. The other tube being normally free, a greater amount of force is exerted, on pressing the bag, by the air on the well ear, than can be employed with safety, even though that air should not be medicated. If, however, in those numerous cases where local stimulation, in addition, is needed, medicated air be used, still greater disadvantage may result. By this method of medication of the mucous membrane lining the air-passages, a greater impression will be made on the naso-pharyngeal part of it than on that portion lining the affected tube and middle ear, although the latter portion of the membrane needs it most. If the large bag be used, in connection with the Eustachian catheter, to introduce either pure or medicated air into the middle ear, the size of the bag is an inconvenient one, and often makes the procedure painful. The amount of force usually employed with this large bag, in the treatment of children, frequently alarms them, even if pain be not produced, and renders it more difficult to treat them.

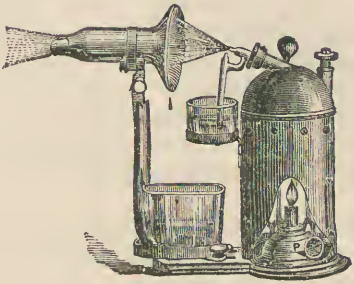
If the nasal douche be used to remove the hardened secretions often found to be present in the naso-pharyngeal space, and obstructing the mouths of the tubes, it is open to the objection that the saline solution employed may be stronger than it would be safe to have enter the middle ear, through the Eustachian tube, as it is likely to do if either the reservoir be placed too high, or the soft palate be removed from contact with the posterior wall of the pharynx during the operation. Acute inflammation of the middle ear, with occasional perforation of the membrana tympani, has thus been produced. If the soft palate remain in contact with the pharynx, that portion of its posterior aspect which is in contact, and which is very often granular and covered with altered secretion, is prevented by its position from being washed by the current as the other parts of the membrane are, thus rendering the application only partial.

In the use of the Eustachian catheter, if hard rubber be the substance of which that instrument is made, it necessitates a variety of shapes of the catheter to meet the great variations found in nostrils. Unless the proper size and right curve of the instrument be obtained, pain will be produced, and failure to reach the tube will frequently result. Heating

the catheter to give it the required curve, delays the operation, to avoid which it is necessary to have a number of different catheters. If alloyed silver catheters be used, they are too firm to have their curve readily changed, and in consequence require the surgeon to keep on hand several of them of different sizes and shapes. If Eustachian bougies be used to open the tubes, their introduction is generally painful and attended with some risk, whilst the results obtained are too often uncertain and unsatisfactory.

With a view to avoid objections incident to the use of these different instruments, I have been accustomed to substitute for the nasal douche a steam atomizer (Fig. 1), using the vapor of some alkaline solution, as

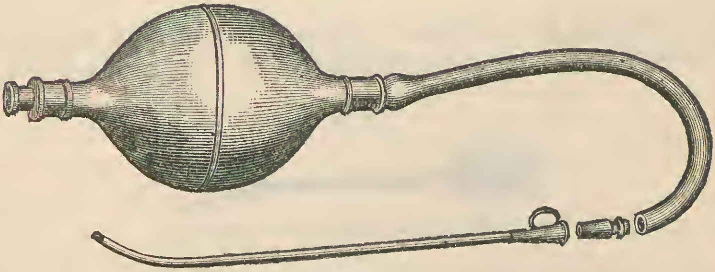
Fig. 1.



Steam atomizer.

of the chlorate of potassium, or of borax, which the patient breathes in through his mouth and expels through his nostrils—thus getting the effect of the warmth, the moisture, and the alkali, to cleanse the mucous membrane of its secretions, and to assist in removing the inflammation. Having thus cleansed and prepared the mucous membrane for further medication, a Eustachian catheter of pure silver (Fig. 2), readily adjustable to the curve required, is introduced. To this is attached, by means of a small hard-rubber tip and an elastic tube, a small rubber bag (Fig. 3),

Figs. 2 and 3.

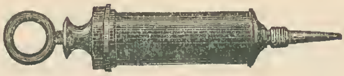


Eustachian catheter and valve-bag.

with a valve such as is used in the local-anæsthesia apparatus. The ordinary "diagnostic tube" ("otoscope," Toynbee) is then introduced into the external meatus of the patient, and into that of the surgeon. Pressure on the valve-bag forces air through the catheter into the middle ear, if the Eustachian tube be open, as is readily recognized by the sound produced. This bag has the advantage of always filling in one direction,

thus avoiding the drawing of mucus into the catheter. If the tube be not open, a small hard-rubber syringe (Fig. 4), with its tip covered with

Fig. 4.



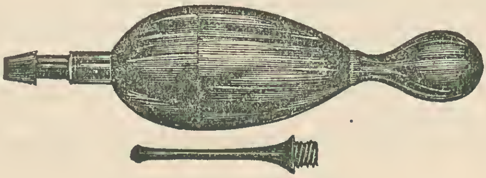
Hard-rubber syringe.

a piece of rubber tubing to adjust it to the expansion of the catheter, is filled with a warm and slightly alkaline solution, with glycerine added, and is inserted into the catheter. With this, the solution is forced into the Eustachian tube, using the liquid as the mechanical means of distending the tube, instead of relying simply upon compressed air (as in the methods of Valsalva and Politzer), or of using bougies.

Experience has shown that if the solution used be not of too irritating a character, and if its temperature be nearly that of the blood, no injurious effects follow its passage into the middle ear. On the contrary, it assists, by dissolving them, in removing the secretions that have frequently dried and remained accumulating in the middle ear and mastoid cells.

Having thus opened the tube, and dissolved the dried secretion, air impressed with iodine may be forced through the tube until the middle ear, and even the mastoid cells, may be impressed by it. This can be done by placing a few crystals of iodine between two pieces of sponge, slightly moistened and inclosed in a hard-rubber bulb (Fig. 5), (such as

Fig. 5.



Buttles's hard-rubber bulb.

Buttles's), attached to a catheter. Air is forced through the sponge by means of the valve-bag above described (Fig. 6). When the lining of the

Fig. 6.

Valve bag and hard-rubber bulb combined.

tube and the middle ear have thus been sufficiently medicated, the catheter may be withdrawn, and a blunt nozzle attached to the bulb containing the iodine. If this nozzle be placed in one nostril, the other one having been closed by pressure, medicated air can be forced in, in the act of swallowing water, as is pure air in Politzer's method—impressing the whole membrane more thoroughly, by means of a smaller bag than that used by Politzer, and with less attendant risk.

By the method here pursued, the surface is readily cleansed, and the

requisite amount of stimulation of the affected parts may be easily and painlessly obtained. Such cleansing and stimulation seem to be the basis of the most successful treatment of this form of inflammation of the middle ear, and thus better results may be obtained than are usually expected in these cases.

The modifications proposed consist, therefore :—

I. In the substitution of the steam atomizer for the nasal douche, to remove secretions from the naso-pharyngeal space and from the openings of the Eustachian tubes, and to reduce inflammation.

II. In the substitution of pure silver catheters for those of alloyed silver, or of hard rubber.

III. In more frequent use of the Eustachian catheter as a means of medicating the Eustachian tube and middle ear.

IV. In the substitution of a warm, slightly alkaline solution, forcibly injected by means of a syringe through a catheter, to open the Eustachian tubes in certain cases, instead of condensed air or bougies.

V. In the substitution of air, impressed with iodine, for irritating liquids, as a topical application to the mucous membrane lining the naso-pharyngeal space, the Eustachian tube, and the middle ear, this medicated air to be introduced through the Eustachian catheter.

VI. In the substitution of a small rubber bag with a valve, designed to inflate the Eustachian tubes, for the larger bag recommended by Politzer for that purpose.

ON THE BEST MODE OF TESTING THE HEARING OF SCHOOL CHILDREN, AND OF PROVIDING FOR THE INSTRUCTION OF PARTIALLY DEAF CHILDREN.

BY

CLARENCE J. BLAKE, M.D.,

INSTRUCTOR IN OTOLOGY IN HARVARD UNIVERSITY.

One of the strongest arguments in evidence of the importance of the subject expressed in the title of this paper, is the fact that, except in individual cases, or where the loss of hearing is so great as to result in deaf-mutism, no provision is made in our present school system for the special instruction of those children whose infirmity, in this respect, gives them, if anything, a larger claim upon the efforts of those to whom is entrusted the laying of the foundation of that mental development which is the basis of the prosperity of a people. To the attainment of that proper degree of mental development which raises the man above the animal, the sound mind in the sound body is necessary; and when one of the channels for communication from without, is either wholly or partially closed, there devolves upon those who have the furtherance of this development in charge, the duty of compensating in one way or another for the loss. How this may be best accomplished in the case in question, is for us to consider.

In a work on the physical and mental education of deaf children, published with the sanction and under the advice of Prof. Von Tröltsch, the author says:[1] The generally received opinion that diminution of hearing in children, in consequence of disease of the ear, is rare, is a mistaken one; indeed, in some localities, the cases of disease of the ear exceed in number the cases of disease of the eye, and moreover they are apparently on the increase; the steadily increasing demands upon the mental capacity, accompanying the advances of the times, bring the defects of hearing more and more prominently forward, because they show themselves to be a decided hindrance to the better education of the child. The results, on its later mental development, of the loss or diminution of hearing in a child, are decided and permanent—affecting the understanding, the character, the self-confidence, and, at a later period, the ability of self-support: mental tools the possession of which is invaluable, and the want of which can never adequately be supplied. In this view, it is a matter of concern that more attention has not been directed to the educational development of partially deaf children.

An examination of a number of cases of partial deafness, occurring in children under sixteen years of age, shows that, with the exception of a majority of those cases in which the disease of the ear has been of a character, or of a degree of intensity, sufficient to so far impair the hearing as to be followed by deaf-mutism, the diseases of the ear in

[1] Franciska Schaeling. Beiträge zu einer richtigen, leiblichen, und geistigen Erziehung gehörkranker Kinder. Thorn, 1872.

children are amenable to treatment, with more or less improvement in hearing, and that the impairment of hearing varies considerably in different cases, and is moreover subject, in any one case, to variation during the progress of the disease. In considering the subject of partial deafness, therefore, we have to deal at the outset with a factor in our problem representing an unknown quantity; each individual case of partial deafness must be, as it were, a law to itself, as far as the compensatory advantages to be accorded to it are concerned. To facilitate investigation, however, two general divisions of the subject may be allowed. The first will include those cases of partial deafness in which the loss of hearing is so great as to interfere with the acquirement of articulation, though not sufficient to permit the classification of the case under the head of deaf-mutism. This division will include those cases in which the diminution of hearing is so decided as to interfere with the independent acquirement of information through the medium of the hearing, and will imply the necessity for special instruction. The second division will include a much wider range of cases, from those in which the hearing is so slightly impaired as to permit of ordinary intercourse, downward through varying degrees of impairment of hearing until the degree belonging to the first division is reached.

Those whose cases come under the first division, form fortunately but a small percentage of all the subjects of partial deafness among children; and a consideration of their needs may be deferred, as secondary to the subject immediately under consideration, and because moreover no provision has been very generally made for their instruction. For the instruction of those whose cases come under the second division, there is, as far as I am aware, no provision made in our public schools, beyond the individual and independent efforts of the teachers. The children who are subjects of partial deafness are, however, sufficiently numerous to warrant some special attention to the subject, with the view of determining the best means for giving them equal educational advantages with their more fortunate companions. To do this will require an examination into the nature of the cause of their disability, and the establishment of rules according to which the degree of impairment of hearing may be determined, that the character of the instruction may be varied accordingly.

An examination into the etiology of partial deafness, shows that the diseases of the middle ear are its most frequent cause in children, and furthermore that a great many cases of partial deafness are due either to the subacute or chronic catarrhal inflammation of the middle ear, or to the purulent inflammation accompanied by perforation of the membrana tympani, which follows the simple acute inflammation, or occurs as one of the sequelæ of the exanthematous diseases of childhood. This general rule is subject to certain differences, in differing classes of society; among the wealthier classes, for instance, who perhaps merit our attention less in this connection, because their children are educated more frequently in private than in public schools, the diseases of the ear accompanied by partial deafness and more or less amenable to treatment, in children under sixteen years of age, amount to but 7.8 per cent. of the whole number of cases of ear disease in children and adults taken together. Of this number, making the 7.8 per cent. of the whole, 76 per cent. are traceable to the exanthematous diseases of childhood, especially scarlet fever, and in 56 per cent. there is found an existing purulent inflammation of the middle ear, requiring treatment, and causing a suf-

ficient degree of deafness to interfere with the patient's participation in the ordinary school exercises, on equal terms with other children.

Among the middle and poorer classes, the proportion of diseases of the ear in children is largely increased, and it is these classes which we have particularly to consider, since they more generally avail themselves of the advantages offered by public instruction. Out of 8715 cases of disease of the ear, examined in patients of this category,[1] 2175, or 24.95 per cent., occurred in children under fourteen years of age. Of this number, 2175 cases of disease of the ear accompanied by partial deafness, 1085, or 49.8 per cent., are recorded as examples of purulent inflammation of the middle ear; 113, or 10.5 per cent. of the cases of purulent inflammation, being due to scarlet fever. As many as 514 cases, or 23.6 per cent. of the cases of disease of the ear in children, are recorded as examples of either acute or chronic catarrhal inflammation of the middle ear. This brief analysis is sufficient to show the much greater prevalence of such diseases of the ear as are liable to induce partial deafness, in the children belonging to those classes in society which depend for their instruction on the advantages offered by our public schools. A more minute analysis of the material offered, which would hardly be in place here, affords interesting information as to the general causes and the average course and results of diseases of the ear in children. It may be remarked, however, that, in the analysis given, only those cases are included in which the deafness was not so decided as to interfere with the acquirement of articulation, or even with the use of the ear as a medium for instruction. The number of cases of positive deaf-mutism, and of cases in which, while there was a certain degree of hearing, it was so slight as to render instruction in articulation necessary, was 107, or, of all the cases in children examined, 4.9 per cent. The average age of all the children examined was about nine years.

We see, therefore, that in a large majority of the cases of disease of the ear occurring in children at an age when they should be profiting by school instruction, the disease is accompanied by partial deafness, and is moreover of a character to lead us to expect considerable variation in the hearing during the progress of the disease, or during the ordinary term of school life. This point is one which should be especially considered in coming to a conclusion as to the character of the instruction to be provided in these cases; we have to deal not only with a different factor, in the different degrees in which the hearing is diminished by disease in different cases, but also with a possibly variable factor in any individual case.

Admitting the necessity for making some provision for the wants of children of this class in our public schools, and excluding, for the present, those cases in which the deafness is of so high a grade that special instruction is absolutely necessary, we have to consider the advisability (1) of establishing separate classes in our schools for the instruction of partially deaf children; or (2) of instituting such a system of inspection as shall lead to a determination of the wants of individual cases, and such a consideration thereof, on the part of the teacher, in addition to the ordinary course of instruction, as will permit of education in mixed classes, compensatory advantages being accorded in cases of partial deafness.

[1] Aural Clinic, Massachusetts Charitable Eye and Ear Infirmary; Statistical Report, Service of C. J. Blake.

The objections to the former course would seem to be—

(1) The encumbering of our school system with an additional department for which especial provision would have to be made. Against this objection it may be urged that initiatory steps have already been taken toward the establishment of separate public schools for the education of deaf-mutes, and the so-called semi-mutes, and that children suffering from partial deafness could be transferred to such schools, thus making use of a department already in process of establishment, and avoiding the creation of another additional department for instruction of only partially deaf children. While the instruction of semi-mutes in the same school with deaf-mutes proper, has certain advantages which have been successfully illustrated in the public schools established for that purpose in Boston, and of which I shall speak hereafter, there are certain aguments against this disposal of the question, and in favor of a different provision for the needs of those partially deaf children who do not at present, and, from what we know of the nature of the diseases which caused their deafness, are but little likely to, in the future, deserve classification among semi-mutes. These arguments are included in the further objections to the establishment of separate classes for instruction, which are—

(2) The moral effect upon partially deaf children of making them, and recognizing them as, a class by themselves, and the exaggerated sense of their infirmity resulting from their being so set apart. The object of the public-school education is to fit the children for the best use of their mental powers in adult life, and to enable them to associate in the world under circumstances which shall make their acquired knowledge best available for their own and the general good; and this object would be in a measure defeated by the encouragement, in partially deaf children, of those feelings with regard to their infirmity which are one of the chief misfortunes of the deaf-mute. To set them apart in the manner referred to, would be to permit an underestimate of their own powers, which, though every effort to counteract it should be made, would necessarily carry its impress into adult life.

(3) The loss of the beneficial association with hearing children, and of a proper spirit of emulation; for since these children are to go out into the world, where they will be judged by the general standard of effort and success, it is best that they should associate in the beginning with those who are to be their companions or their opponents in the struggle for existence, and that they should be urged rather themselves to compensate for their defect than to expect compensation at the hands of others. More precisely, the association with hearing children helps toward the overcoming of certain faults which are common in children who are partially deaf. Partially deaf children are very apt to become heedless and inattentive; from not hearing occasionally, they get into the habit of not expecting to hear, and make less mental effort to combine such sounds of the voice, for instance, as they do hear, or to supply the deficiency of those which escape them. The ultimate effect of this habit, if uncorrected, on the mental development, is very decided; for, in these cases of partial deafness, nature does not seem to have made that effort at compensation which is so strikingly illustrated in the quickened perceptive powers of the deaf-mute. Again, many partially deaf children are almost morbidly sensitive on the subject of their infirmity, and of their implied inferiority: a feeling which, if permitted or encouraged, has a very unfortunate effect upon the child's efforts in its studies,

and subsequently upon its efforts at the self-instruction and self-control of adult life. The association with hearing children, and that degree of participation in class exercises which is possible under certain favoring conditions, tend to overcome the self-consciousness which is always more or less of a barrier in the way of advancement.

(4) The final argument against consigning partially deaf children to a special class or school, lies in the fact, already mentioned, that the imperfection of hearing is not a fixed factor in the problem. In the majority of the cases included in the analysis given, the hearing was susceptible of improvement, and in all of them was subject to temporary variations during the progress of the disease or course of treatment.

The best fulfilment of the second course under consideration, education in mixed classes, necessarily entails a determination of the degree of physical disability of the pupil, for which compensation is to be made. This may be accomplished in two ways, of which the best is by means of a competent professional examination of each case of supposed or evident deafness occurring in the pupils of, or those presented for admission to, a public school. This course offers the advantage of determining with accuracy, not only the degree of hearing, but also the character of the disease which causes the deafness, the amenability of the case to treatment, the probable course and duration of the disease, and its probable, ultimate effect upon the hearing; in very many cases, as may be judged from the statistics given, the need of treatment would be detected where otherwise it might have passed unnoticed. The establishment of the office of medical supervisor of public schools, the position to be filled by a qualified medical man who should devote his time to the duties of his office, would cover this in addition to many more important needs in connection with the hygiene of our public schools.

In default of this more thorough method of examination, the object, as far as a determination of the degree of hearing is concerned, may be accomplished by the teacher, to whom may be committed the task of classification according to certain simple rules for testing the hearing, applicable to all cases. The ordinary tests for the hearing, by means of the watch and tuning-fork, or the use of other musical tones, are each of precise value only when taken in connection with a competent examination into the condition of the diseased organ, and a careful consideration of points of which only a professional observer is competent to judge. Careful tests of the hearing by means of the voice, however, in connection with one or other of the tests mentioned, would enable a competent teacher to determine whether a subject of partial deafness could be left to participate in the ordinary school-room exercises, in common with other children, or whether it would be necessary to give the child special attention.

Following, for instance, the suggestions to be drawn from the observations of Oscar Wolf on the musical value of the vowel and consonant sounds, and the effect which diseased conditions of the ear have upon the perception of consonant and vowel sounds in combination, it is possible to arrange a series of test-words which may be used by teachers as a standard test in schools.

Each teacher may be provided with a form for tabulation of cases, which is to be preserved as a record of the degree of hearing power, accompanied by instructions as to the method of conducting the examination. These instructions should include a clear definition of the precautions to be taken in order to arrive at a correct estimate of the hearing,

the personal opinion of the teacher being required only in remarks upon any other symptoms of disease of the ear, such as otorrhœa for instance, which would seem to indicate the advisability of immediate treatment. The watch and the tuning-fork, or the tones of a musical instrument, may be employed as subsidiary tests, but the main reliance should be placed on tests with the voice, for not only does the human voice, considered as a musical instrument, fulfil certain conditions as a test not otherwise attainable, but it is the voice of the teacher especially which the child is required to hear, and for the accurate hearing of which it is necessary that the child should be placed in such a position in the school-room as shall serve to compensate for its diminished hearing. As a rule, therefore, the tests indicated should be repeated on the transference of a pupil from one room, or one teacher, to another, for every human voice has its peculiarities of pitch and quality, which give it, estimated as a test, a hearing value of its own. These tests also may be repeated at intervals, without proving a great addition to the labors of the teacher, for the purpose of determining the average degree of hearing.

The hearing distance for the voice having been determined, the point in the school-room at which all the test-words are distinctly heard, should determine the position of the seat to be assigned to the pupil, such proximity to the teacher as shall enable the particularly deaf pupil to hear the teacher's voice as readily as a pupil with perfect hearing at the extreme limit of the room, being one of the compensatory advantages which his diminished hearing demands. Furthermore, the attention of the teacher should be directed to the necessity for giving such cases special attention, in such manner as to supply the loss of parts in class exercises which the pupil may have but imperfectly appreciated. A lack of knowledge on the part of teachers of the great obstacle which partial loss of hearing may present to a proper appreciation of school exercises, and the establishment of a fixed standard of instruction to which all the pupils in a class are required to conform, results in added labor on the part of the partially deaf pupil, without the consideration which his imperfect ability in this respect should command.

Passing from the consideration of those cases of partial deafness which may be provided for in the manner above proposed, we have to consider the needs of that more unfortunate class whose hearing is so far impaired as to render special instruction absolutely necessary. The objections which were made to the separate instruction of the majority of partially deaf children, do not apply here. One of the earliest and most unfortunate consequences of extreme deafness, in children, is the impairment of speech; with the loss of hearing is lost the medium through which the knowledge of speech is acquired, and the child gradually lapses into the use of gestures (to proclaim its wants) and the production of inarticulate sounds. To retain or to educate the power of speech, is, however, but one of the objects to be attained by special instruction; some means must be supplied which will compensate as far as possible for the loss of hearing, and prove another medium through which the child may receive the same education as that afforded hearing children in the common school. The sense of sight may, in these cases, be called in aid, and the child may be taught to hear, as it were, with the eyes.

Various systems for instruction in this so-called, visible speech, are in operation, and their results, as far as I have been able to observe them, are not merely encouraging, but eminently successful. Furthermore, as every possible means of imparting instruction should be made available,

in addition to education in lip-reading and articulation, such hearing as the child may possess should be utilized by the employment of artificial means, if necessary, for the readier conveyance of sound to the ear. As a result of practical experience, and not merely upon theoretical grounds, the use of the hearing-trumpet, of one kind or another according to the requirements of the case, may be advised during school exercises; indeed, in many cases, the use of such an instrument tends to improve the hearing not merely during the time of its use, but generally, the subjection of the ear to sound waves of larger amplitude either increasing the vibratory power of the sound-conducting apparatus of the middle ear, or acting as a stimulus to the auditory nerve. The proper application of these auxiliaries to instruction, necessitates therefore the formation of a separate class, for the benefit of which, as has been said, the public deaf-mute school, which now forms an important part of the Boston school system, and which must in time be engrafted upon the public school system of other large centres, may be made available.

In the Boston school, the children are divided into two general classes, those who are total deaf-mutes, and those who are semi-mutes. Children in the latter class are instructed in articulation, for the purpose of overcoming faults which always exist where the hearing is imperfect, and in lip-reading, that they may learn to understand conversation from sight as a substitute for hearing. Such hearing as remains to them is also made useful in conveying ideas as to the formation of vocal compounds, by means of an ear-trumpet, if necessary, or by speaking directly into the ear. As the total deaf-mutes improve in articulation and lip-reading, they are advanced to the class consisting of semi-mutes, partly because the grade of instruction has become the same, and partly that they may profit by the example of those more fortunate companions who have had the advantage of having a little speech or a little hearing to start with. On this plan, the Boston school has now been in operation for five years, with increasing success and increasing evidence of its great value; it now provides for about sixty pupils, all of whom are instructed in lip-reading and articulation, the method employed being the system of visible speech introduced in this country by A. Graham Bell.

The conclusions drawn from a study of the subject of this paper, may be summed up as follows:—

I. The frequency of partial deafness in children, during the period of school life, renders it advisable to make some definite provision in our public school system for compensatory instruction.

II. Since partial deafness is a comparative term, some provision should be made for a proper determination of the degree of disability.

III. This may be best accomplished either by establishing a series of speech-tests, to be used by the teachers, or by instituting competent medical examination at the hands of a medical supervisor of schools; and the creation of such an office in connection with our public school system is strongly urged.

IV. Partially deaf children, whose hearing is not so defective as to require special instruction in articulation and lip-reading, are better taught in mixed classes with those who hear well, compensatory advantages being allowed them according to their degree of disability.

V. Partially deaf children, whose hearing is so defective as to interfere with the natural acquirement of articulation, and to render the ear of little or no value as a medium for hearing, should be accorded the ad-

vantages of special instruction, of which education in articulation and lip-reading should form a part.

Discussion on Dr. Blake's Paper.

After the reading of the preceding paper, Dr. Charles H. Burnett, of Philadelphia, said:—I would ask Dr. Blake if he has noticed, in the schools visited by him, whether adult mutes have been taught to talk?

Dr. Blake said:—I have noticed, especially in the Northampton schools, that pupils who have reached the age of sixteen years, for instance, are taught to talk with very great difficulty. A deaf-mute taught in the sign language, learns to think in a language different from ours. One sign may convey two or three meanings, and its signification often depends upon the context. The deaf-mute's arrangement of words in sentences resembles more closely that of the French, than that of the English, language. The success of deaf-mutes in the acquirement of articulation is sometimes very astonishing. The sound of the voice is at first harsh, and articulation is imperfect. But modulation of the voice is attained, in default of hearing, by the pupils learning to observe the sensations produced by speaking in the throat, by which means they soon learn to appreciate the difference between the rising and the falling inflection. There have been instances in which English deaf-mutes have been taught with such success that they have learned to speak French and German fluently, and to sing harmoniously.

ON AURAL VERTIGO WITH VARIABLE HEARING.

BY

CHARLES H. BURNETT, M.D.,

AURAL SURGEON TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

VERTIGO from disease of the semicircular canals has been fully recognized ever since the publication of Ménière's papers on the subject. Guided by the description of his case, and, more recently, by the investigations of Flourens and others respecting the physiology of the semicircular canals, the tendency among medical men has been to ascribe all cases of acute aural vertigo, not directly traceable to some irritation in the external auditory canal, to disease in the labyrinth, preference being given to the semicircular canals as the seat of the direct lesion.

Without entering into a discussion respecting the precise location of the lesion in labyrinthine vertigo, it can be comprehended why the deafness which is so marked a symptom of this disease, may be permanent. In fact, if the direct lesion be in the labyrinth, as it undoubtedly is, in true Ménière's disease, one cannot understand how the deafness can fail to be permanent. In the affection known as Ménière's disease, called also labyrinthine vertigo (Hinton), the chief symptoms are sudden tinnitus aurium, vertigo, reeling, falling without loss of consciousness, nausea, vomiting, and sudden, total, and permanent deafness in the affected ear. The other symptoms may occur in paroxysms for longer or shorter periods. But there are on record a few cases, and doubtless many others have occurred which have been recognized though not recorded in literature, in which all the above-named symptoms have existed, excepting the permanence of the deafness. Mr. Hinton records such cases,[1] with the statement that the recovery of the hearing was perfect, and then raises the question "were they not caused by muscular spasm?"

Especially noteworthy is that form of acute aural vertigo in which the hearing diminishes during the paroxysm, improves during the interval, and finally is restored when the paroxysms of tinnitus, vertigo, etc., cease to recur. In such cases, it is manifest that the direct lesion cannot be in the labyrinth, and the question might be asked, "Are not such cases due to a spasmodic affection of the muscles of the tympanic cavity?" Future investigations may show that such cases are caused by undue inward pressure of the stapes, which is brought about either by a tonic contraction of the tensor tympani, so powerful as to overcome the equilibrium normally existing between the latter and the stapedius, or by a relaxation of the latter muscle, which permits the normal tensor tympani to act without the antagonistic counterbalance of the stapedius. As tending to answer in the affirmative the question which I have proposed, I would cite the following case:—

Mr. X., aged 41, single, a stock broker, was brought to my door in a carriage on May 8, 1875, apparently in collapse; upon approaching him, however, I found him conscious, but very pale and weak, and his surface cold and

[1] Questions of Aural Surgery, pp. 261–262.

clammy. I was asked to accompany him immediately to his home, and while doing so learned from him that he had been suddenly attacked about an hour before, while attending a meeting of the Board of Brokers, with sudden and intense tinnitus aurium and vertigo, with entire inability to stand, and that he had finally vomited, but that, during all the time of this most disagreeable attack, his mind had been perfectly clear. I found his pulse about 75, but very weak, and he stated that there was still some vertigo, but that the buzzing in the ear had given place to a "stunned feeling" in the head, attended with a boring sensation which seemed to start behind the auricle, and to extend inward to the centre of the head. There was no complaint of altered hearing at this time, but I found that the hearing of the watch was reduced to $\frac{6}{60}$ in. in the affected ear.

The patient was put to bed, and, as his surface was very cold, a little warm brandy and water were given, and warmth was applied to his feet. In about an hour, the vertigo became much less, the head was more comfortable, and the face lost its intense pallor; pulse 80. The patient then stated that, four or five weeks before, he had noticed occasional attacks of slight tinnitus in the left ear; this was brought on or increased by cold air blowing on the ear. A week or two afterwards, he observed some dizziness with the noises in the ear, and also some confusion in hearing, especially during the playing of the organ and the singing in church. The patient had had a good musical education, and he stated that he heard all notes sharpened (heightened) in pitch, in the left ear, which, of course, produced subjective discord with what he heard in the other ear. This was also true for the tuning-fork, *small "A,"* which seemed to him higher in pitch in the left or affected ear. As the tinnitus passed off, however, notes appeared once more to have their true pitch.

With the cessation of the tinnitus, and with the return of the ability to hear notes in their true pitch, in the affected ear, the hearing also improved for the watch, rising from $\frac{6}{60}$ in., during the attacks, to $\frac{20}{60}$ in. as the paroxysms ceased. This variation in the ability to hear the watch occurred not only once, but repeatedly; and it was also observed that a mantel-clock, easily heard by the patient across the room in the affected ear, when unattacked by the paroxysms, was not heard during the latter. The left membrana tympani was more retracted than the right. The Eustachian tubes were easily inflatable; the fauces normal. There was a history of some stuffiness in the now affected ear, once after sleeping all night upon the ground, when in the army during the war. But beyond this, the patient knew of nothing out of the way in the ears.

The patient remained in bed four days: On the *first* day, it was found that rest in a reclining posture relieved the tinnitus and vertigo, but on the *second* day, a severe attack came on in bed, and lasted several hours. On the *third* day, an attempt to rise brought back all the symptoms, which were finally relieved by vomiting. On the *fourth* day, another severe and long attack occurred. On the *fifth* day, the patient observed that the "stunned feeling" in the left side of the head, alternated with the tinnitus; the latter invariably preceded the attacks of vertigo, beginning as a low and distant singing or ringing, and increasing to a loud roaring, which culminated in the vertigo and nausea. On the *sixth* day, there was no attack. On the *seventh*, he felt very much better until 11 A. M., when a severe paroxysm occurred; as a rule the attacks occurred in the afternoon or evening. On the *eighth* day, there was no attack, but on the *ninth* there was a light one. Again, on the *tenth* day, there was no attack, but at midnight of the *eleventh*, there was a very severe paroxysm of tinnitus and vertigo, which woke the patient up. Closing his eyes had always aggravated the vertigo, and he now found that the darkness of his room greatly increased the dizziness. Being entirely alone, and unable to help himself, he was obliged to call for a light in order to gain some relief from the terrible discomfort brought about by the vertigo. He felt as if his whole body were being borne through space. Usually the apparent motion of surrounding objects, during the attacks, was around the patient from the right, over his

head, to the left, under him and up again—that is, in a circle, the plane of which correspended pretty closely with that of the superior semicircular canal, and about at right angles with the antero-posterior diameter of the head.

The severe attack of vertigo on the *eleventh* day, extended into the *twelfth* day, but there was no vomiting. On the *thirteenth* day, there were two attacks, but no vomiting. On the *fourteenth* day, there were again two attacks, but they were light, and there was no vomiting. On the *fifteenth* day, there was no attack, but on the *sixteenth* day there was one very light and short paroxysm of tinnitus aurium and vertigo. On the *seventeenth* day, there was no attack, but on the *eighteenth* there was a very light one, which was the last the patient had. The hearing now became normal.

Before these seizures came on, the patient had been under intense mental excitement, and his general health had failed from the time of the financial panic of 1873 to the date of his first attack of vertigo. He had also been, in this weakened and nervous condition, obliged by his business to endure the intense and peculiar noise of the stock-brokers' board, and also to strain his ears to hear, and his vocal organs to perform his share of, the bidding which goes on in such places.

The treatment consisted in general support, with the administration of good food and some alcohol, together with large doses of bromide of potassium during the persistence of the paroxysms. As the latter diminished in severity, iron and quinine were given. On the sixth day of the disease, twenty grains of bromide of potassium were given every hour, and this was continued until the tenth day, when the patient took but ten grains every two hours. On the sixteenth day, the bromide was taken every three hours, and kept up in this way until the paroxysms had evidently ceased.

The patient went to Europe, made a short tour, and returned to business in the autumn, about six months after his first attack of vertigo. There has been no severe return; this spring, when he was under considerable excitement once more, he had a slight return of the tinnitus, and a slight tendency to vertigo, but no sickness of stomach. A few days of rest, and from six to eight grains of quinine daily, dissipated all these unpleasant warnings, and the patient has been able to continue his attention to business.

This case of aural vertigo is especially interesting on account of the variable hearing which was so prominent a symptom during the disease, and also on account of the recovery of hearing which ensued when the paroxysms of tinnitus, vertigo, nausea, etc., ceased to recur. In fact, these features of the disease would tend to place it either in the list of those of infrequent occurrence, or among those the true nature of which is not often recognized, and hence undescribed. It is well known that the prominent symptoms of aural vertigo, viz., sudden tinnitus, intense dizziness, alteration in the hearing, nausea, vomiting, and falling, without loss of consciousness, may be caused by the irritation set up by the presence of a foreign body in the external auditory canal. But here the cause is easily recognized and removed, and upon its removal the recovery is complete. The same general symptoms are notoriously characteristic of labyrinthine vertigo (Ménière's disease), but there the deafness is sudden, total, and permanent, though the paroxysms of vertigo may cease to recur.

I have lately seen two cases of tumor in the brain (the one proven *post mortem*, the other diagnosed as such, but the patient still living), in which the new growths produced symptoms very much like those usually attending labyrinthine vertigo. Still, there were points of differential diagnosis in these cases.

The subject of the first, a woman, suffered for many years with most of the distressing symptoms of Ménière's disease, with the exception that she became

slowly, entirely deaf, whereas the deafness in true, acute, labyrinthine vertigo is sudden, intense, and permanent. In this case a post-mortem examination revealed the presence of two tumors, one on each auditory nerve; on the right side, the morbid growth, as large as a chestnut, seemed to have obliterated the nerve, and extended into the porus acusticus internus, and apparently into the labyrinth. The microscopic examination of this growth has not yet been made. On the other side, the tumor, a smaller one, seemed to have simply grown in the auditory nerve, between the brain and the internal auditory canal.

In the second case, that of a man, the presence of a tumor of the brain has been diagnosed; the patient has some of the symptoms of aural vertigo, but there is permanent alteration of the gait, which is not characteristic of Ménière's disease, nor of any form of aural vertigo originating in the tympanum or external ear. Furthermore, the patient is not very hard of hearing (both ears are affected, as they were in the first case), and, though he has constant tinnitus and paroxysms of vertigo, he can always relieve the giddiness by sitting down. While these cases may be classed under the head of aural vertigo, they are manifestly not cases of primary labyrinthine disease.

The case of Mr. X., given above, presented all the marked symptoms which are found in aural vertigo of the labyrinthine variety, excepting the sudden, total, and permanent deafness; but this difference would exclude it entirely from aural vertigo due to primary labyrinthine disease. The case certainly did not originate from irritation in the external auditory canal, and that it could have had its origin in cerebral tumor, is entirely out of the question, not only because such a supposition would be unwarranted by the symptoms, but also because recovery finally ensued. May it not be, however, classified as a case of aural vertigo of the tympanic variety, in which the primary lesion lay most probably in the muscular structures in the middle ear? As tending to cause such a disturbance, I would mention the intense strain on the vocal organs as well as on the muscular accommodation of the tympanum, which necessarily occurs among those who frequent the brokers' board, where bidding aloud and listening to bids go on.

In conclusion, I would suggest that, in future investigations of this most interesting and important disease, it would be well to make "aural vertigo" a general term; then four varieties of that disease could very easily be described, according to the anatomical situation of the cause, for there might be (1) Aural vertigo from external irritation (in the external ear); (2) Aural vertigo from tympanic disease (Mr. X.'s case is an example); (3) Aural vertigo from labyrinthine disease (Ménière's disease); and (4) Aural vertigo from central irritation (cerebral tumors implicating the auditory nerve). Such careful distinctions in diagnosis are extremely important, as aiding in prognosis—this being far more favorable in the first two than in the other varieties.

ON THE SEVERAL METHODS OF EDUCATING, AND ON THE SELECTION OF PROPER SCHOOLS FOR, THE DEAF AND DUMB.

BY

LAURENCE TURNBULL, M.D.,

FELLOW OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE; AURAL SURGEON TO JEFFERSON COLLEGE HOSPITAL; PHYSICIAN TO THE DEPARTMENT OF DISEASES OF THE EYE AND EAR, HOWARD HOSPITAL, PHILADELPHIA.

The lot of the uneducated and ignorant deaf-mute is sad indeed; cut off from intercourse with his fellow-man by loss of speech, and unable to obtain instruction or amusement from such intercourse, or through books, he is left to "Nature," and is governed by naught but his animal passions and appetites. It is no wonder then that, when these latter are in full development, he becomes allied to certain of the brute creation. From my own dissections of the brain of the deaf-mute, as from those of many careful observers, it is rendered probable that the deaf and dumb are capable of receiving and retaining as great an amount of intellectual knowledge as their hearing brothers or sisters, provided that adequate instruction be made available through the eye.

As early as the fifteenth century, some effort was made to teach deaf-mutes, but it is to the sixteenth century that is due the great honor of having been the period of jubilee to the deaf and dumb; and to the Abbé de L'Epée was given the great gift of teaching deaf-mutes by a symbolic language, so that they might know good from evil, have intercourse with a select few of their fellow-men, and above all acquire such aspirations after true knowledge as would fit them for a happy home here, and for a better world above. Another devoted man, the Abbé Sicard, who took up the clue already furnished by de L'Epée, adopted sign-language, and enlarged, improved, and reduced it to a system. The knowledge of this valuable method soon crossed the Atlantic, and its advocate, the Rev. Thomas H. Gallaudet, D.D., founded the American Asylum at Hartford, Conn. (1817), and, soon after (1820), M. Clerc (one of the favorite pupils of Sicard), who came over with Dr. Gallaudet, organized the Pennsylvania Institution for the Instruction of the Deaf and Dumb, in Philadelphia. This institution has sent out, since its organization, 1700 pupils, well educated, and with a careful moral training which has been of inestimable advantage to them and to the community at large. Germany was not long after France in this philanthropic labor, for, in 1760, Samuel Heinicke, a Saxon by birth, developed the "artificial method" of instruction for deaf-mutes. The principal aim of this good man was to improve the "French system," and to endeavor to cultivate whatever might remain of speech, by developing the latent power which exists in all save a very few. In the early stage of this system, artificial signs are absolutely necessary; but when these have been acquired, they are to be employed only as a ladder to reach the higher department, where the finger-alphabet and other artificial signs are no longer required. When successfully taught by this system, pupils are enabled to think in the

idioms of the language of their country, to hold audible conversation, and so understand much that is spoken to them, being thus rendered practically less deaf, and actually less dumb.

Another advance which has been made in the further improvement of the mode of instruction of the deaf-mute, comes from England, in the system known as "Bell's Method of Visible Speech," which, having received but little attention in the country of its origin, was brought by its author to the United States, where it has been received and adopted in seven of our forty-eight institutions, and with the most gratifying results. I do not find fault with what has been done under the old methods, but rather rejoice that so many thousands of deaf-mutes have received the advantages of an education by means of the sign language, and of articulation taught by the German method. I would also state that the United States have a "National College" at Washington, where more advanced studies can be pursued, and where young deaf-mutes are graduated with a standing and scholarship not inferior to that achieved by the graduates of ordinary colleges. This institution bears to others for the deaf and dumb, the same relation that colleges bear to schools and academies. Many of the graduates of this college have received appointments as teachers, while others are editors, authors, and writers, or are found in the various government offices, in the exercise of duties which they are quite capable of performing in an entirely satisfactory manner. In our Centennial Exhibition will be found some admirable pictures executed by deaf-mutes, as well as other products of their pencils and pens. They are also capable handicraftsmen, and are to be found in our shops and factories, as well as in the Industrial Homes founded in this city for their special benefit.

Bell's method or system of visible speech gives the pupil, by means of drawings, etc., a knowledge of the concealed parts of the mouth and throat, which are used in articulation, as also of the movements of the various parts, so that the pupil is thus better able to gain conscious control over them. This method of writing any sounds that the pupils may utter, serves to interest them in the practice of the elements and combinations, thus giving them great power over their organs of speech, and obviating the necessity of informing them that a sound is wrong if it is not the one which the teacher wishes to obtain. It is the practice of those who teach this system to write all sounds in the visible speech-symbols, and especially those that are essential in English speech. The symbolizing of odd sounds also leads the pupil to think and study about the parts of the mouth that produce them.

I shall now discuss the following questions: (1) What is the best method of classifying deaf children, and is it advisable to place them in ordinary, or in special, schools? and (2) How many deaf-mutes are capable of receiving Bell's method of instruction, and should the attempt be made to instruct all deaf-mutes by articulation, or by the sign language only? Not having heard Dr. Blake's paper, I shall attempt to answer these questions from my own personal observations.

If a child can hear sufficiently well to understand the teacher when near him, the ordinary school is, for him, decidedly better than a special school. Children sometimes become deaf after having learned to talk and read; such children may profitably attend an ordinary school, provided that the parents or teacher take time to explain the lessons; but if this be not done, the child will often recite in a parrot-like manner, without understanding what he has learned, and will go over a great deal

of ground with very little profit. This has been the experience of teachers of deaf-mutes, even when the pupil has learned to read quite well by observing the lips of the speaker. Congenital deaf-mutes, attending an ordinary school, may learn to write, or rather to copy, and may perhaps get some idea of numbers; but the teachers of such schools do not know how to reach their pupils' minds, even if they have the time to teach them. As a rule, such children might as well be at play, except that school occupies their time and their thoughts. Another advantage, however, which is gained for the deaf-mute children, is in their mingling as much as possible with those who hear.

If a child cannot profit by the instruction given in an ordinary school, let him if possible have a private teacher, but not necessarily in his own house, as he is not always subject to the best government there. If he needs stimulating, it may be well to place him in a class with four or five others of a suitable degree of advancement; and if this cannot be done, he may be placed in a school or institution where the instruction is especially adapted to the deaf.

If children are too deaf to profit by the common school, and yet have sufficient hearing to have acquired speech through the ear, instructors of the deaf are nearly or quite unanimous in the opinion that they should be taught by articulation and lip-reading. The experience of the teachers would lead them to say, "Let the attempt be made, if possible, to teach *every* deaf child in this way." Of 116 pupils in the "Clark Institution for Deaf-Mutes," three have been dismissed as incapable of learning articulation and lip-reading, and one because she required more individual instruction than could be given her. The latter, however, has since been taught, so that speech and lip-reading are her means of communication in her own home. Some of the remaining number of pupils (congenital mutes) speak imperfectly, but in every instance well enough to be understood in their own homes, while some of the indifferent speakers are fairly successful in lip-reading, an acquisition as valuable as that of speaking. Many congenital mutes speak so as to be understood by strangers, and will probably be able to make speech and lip-reading a successful means of communication throughout the world. Of the 116 pupils at the above-named institution, one-third are semi-mutes or semi-deaf, although some of those so classed have not had hearing enough to learn to talk.

My object in writing this brief paper has been: (1) To excite a greater degree of interest, in physicians, for the deaf-mute, with an endeavor on their part to prevent deafness, and so diminish the number of deaf-mutes; (2) To induce a more conscientious study and treatment, by physicians, of the ears of their patients, when the latter are attacked by scarlet or typhoid fever, cerebro-spinal meningitis, or obstruction of the Eustachian tubes as the result of measles, diphtheria, tonsillitis, or syphilis; (3) To lead physicians to give the systems of instruction pursued in our various institutions for the deaf and dumb, a certain amount of study, so as to be able to recommend intelligently to patients, their relatives, or friends, the best method for each individual case; and (4) To induce physicians to recommend that there should be appointed by the governor of each State, a commissioner, to collect, examine, and classify the deaf and dumb, so that all who are found to possess any degree of hearing, or any remnant of speech, may be taught articulation by the method of Bell, and that those who are unable to profit by this system, may be taught the language of signs, natural or acquired.

To aid them in their arduous work, I have recommended to some of our teachers of deaf-mutes, that their pupils should use mechanical appliances for improving the hearing power. By speaking or singing different vowels into one of these aids to hearing (tubes or trumpets), we can determine how much hearing the pupil possesses, and, if he be able to distinguish one vowel from another, a continued use of this mechanical aid may ultimately enable him to utilize audition as an auxiliary to vision. I have known very deaf persons, by the aid of this means alone, to have had their hearing so much improved that they could distinguish all ordinary sounds, and, by some effort, enter into conversation. Another important mechanical aid to persons who are deaf from diseases in which the tympanic membrane is lost, in part or in whole, but in which the inner small bone (the stapes) still remains, or in whose ears the bones have become stiff or anchylosed, is the pellet of cotton, moistened and applied near to the bones, or against the stapes, so as to bring the parts in closer contact with external vibrations, and thus cause the sounds to be transmitted to the auditory nerve.

In conclusion, I have added, chiefly from German authorities, the most recent views on the subject of phonation, knowing how much interest this subject is exciting in the minds of both physicians and teachers of the deaf and dumb, at the present day. Some writers have endeavored to prove that the brain molecules of the deaf and dumb differ from those of persons who hear; but, as I have already stated, the brain is rarely affected in those that are deaf, while, on the other hand, in many instances of extensive disease of the brain, not involving the auditory nerve, deafness has not resulted. Occasionally the spine is diseased, or the nerves which, coming from that great centre, give power to the tongue and larynx, thus rendering the deaf-mute unable to articulate, no matter how much instruction he may receive. Section of the spinal accessory, or of the inferior laryngeal nerve, entirely destroys the voice, so that these may be termed the true vocal nerves. If, therefore, the centre of phonation is situated in the spinal cord, it is plain that it cannot be found in the brain; anencephalous children have been known to scream under the influence of external excitation or internal pain. The centre of the memory for words, appears to reside in the brain, and attempts have been made to fix its seat in the anterior lobes, but the observations made on this subject are as yet contradictory. Each centre is independent of the other, for a cry may be easily uttered when articulation is very difficult. *Amnesia*, or the loss of memory for words, therefore, must be distinguished from *aphasia*, or the loss of power to pronounce them; the patient suffering from aphasia can still write his thoughts, while in amnesia he can only express himself by drawing a representation of the object to which he wishes to refer.

ON BATHING, SWIMMING, AND DIVING, AS CAUSES OF AURAL DISEASE.

BY

LAURENCE TURNBULL, M.D.,

FELLOW OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE; AURAL SURGEON TO JEFFERSON COLLEGE HOSPITAL; PHYSICIAN TO THE DEPARTMENT OF DISEASES OF THE EYE AND EAR, HOWARD HOSPITAL, PHILADELPHIA.

Swimming and diving in cold water seem to me to be important and frequent causes of disease of the external auditory canal and anterior surface of the membrana tympani, as also of the middle ear, though bathing in river or sea water is, when wisely and properly regulated, both healthful and pleasant. The evils attending bathing and swimming in cold water are the entrance of this cold fluid, not only into the external meatus, but as far as the membrana tympani, causing inflammation of the lower portion of the auditory canal, and of the anterior surface of the tympanic membrane. But a still greater evil is from sudden deglutition, during diving or swimming, by which—the mouth, nose, and pharynx being filled with cold water, and the mouths of the Eustachian tubes open—a portion of the water passes into the middle ear. This result rarely occurs in expert swimmers or divers, but is most common in beginners, who suddenly, from cold, or the shock of the contact of the water, breathe or swallow in a sobbing manner. I have, however, known it to occur in old and experienced swimmers while plunging headforemost, owing to the intense coldness of the water—the act of deglutition being entirely involuntary.

If the water is not removed by placing the head to one side, and drawing the external ear forcibly outwards, shaking the head at the same time and opening the mouth, it is apt to cause inflammation, with the formation of pus, followed by perforation of the membrana tympani; or the inflammation, if neglected, may pass inwards to the cochlea and labyrinth, and, implicating the brain, may terminate in death.

It is a well-recognized maxim among those who devote special attention to diseases of the ear, that no cold fluid should be allowed to enter even the external auditory canal; still this important fact is not sufficiently recognized by the profession at large. The entrance of warm water into the ear is less objectionable, but even this is not quite free from danger, and has its disadvantages; and the water should in all cases contain a few grains of a saline ingredient, like borax, soda, or common salt, when employed in washing out the ear. The symptoms of water in the middle ear are, in the first stage, an uncomfortable sensation, followed by earache or pain, which after a time becomes agonizing, and is accompanied with great tenderness behind the auricle. In proof that water in the ears is injurious, and causes deafness, I might cite a number of instances, and it is a well-known fact that dogs which are *thrown* into water become deaf.

Many cases of this form of disease, in its chronic stage, come under treatment during all seasons, but acute cases, from swimming and diving, occur during the summer months, and chiefly in boys from eight to six-

teen years of age; a much smaller number occurring in the fall and winter. If the acute form be promptly treated, entire recovery takes place; but should the case not be seen until after the chill, it is always followed by a discharge of shorter or longer duration. In cases not recognized, the symptoms of violent headache, furious delirium, and coma, give the physician the impression that disease of the brain is present, and the case thus improperly treated terminates in death. The morbid condition in the first stage consists in acute inflammation of the extremely delicate mucous membrane lining the middle ear. This inflammation is followed by effusion of fluid, and, after twenty-four hours, by the formation of pus; it is in every instance attended by fever, with swelling and inflammation of the nasopharyngeal space, and great pain. If this fluid or pus be removed by incision into the membrana tympani, followed by the use of the air douche, and injections of hot saline water, the patient recovers, and the ear is saved. The patient is apt to remain deaf for several weeks, and the local application of tincture of iodine, with or without some anodyne, brushed around the back of the auricle, facilitates the removal of the inflammatory thickening. To diminish the discharge of pus, should it continue, we may employ a powder of salicylic acid and starch, blown into the meatus and after a time washed out, and reapplied twice a day, until the discharge shall have ceased and the perforation have become closed.

THE PRESENT CONDITION OF THE EVIDENCE CONCERNING "DISEASE-GERMS."

BY

THOMAS E. SATTERTHWAITE, M.D.,
OF NEW YORK.

THE object of this paper is to give a sketch of the prominent theories now held as to the nature of disease-poisons. It seems hardly necessary for me to say that the short space of time at my disposal will prevent me from attempting to furnish either a detailed account, or even a review, of the ample material that may be brought to bear upon these matters. I desire, however, to state this clearly at the outset, because I am sure that in the presence of the vast number of observations that have been made, especially during the past few years, nothing short of a very extended treatise could be made to fairly represent the whole subject. Fortunately, my task is limited by the title of my paper, but I find myself at the same time in the difficult position of one who is called upon to define the proper limits of the subject, or, in other words, to mark out the debatable ground.

In doing this, I have thought it desirable to direct the attention of the Section chiefly to a certain number of important topics bearing upon the subject, as in this way we can get a better idea of its present status, and I have naturally included among the topics those with regard to which I have had the most personal experience.

It is a matter of regret that I shall be obliged to omit many facts of historical interest, as well as the names of well-known men, who, like Pasteur, Sanderson, Salisbury, and others, have enriched the field by original research. I shall also have to run the risk of appearing dogmatic, in assuming that certain questions have virtually been settled, or that others do not concern us. I shall thus take it for granted that the minute, vegetable organisms, called bacteria, exist pretty generally in

nature, both in and out of the body; and, following the acceptance of this idea, that the question of spontaneous generation need not be introduced into the present matter in hand.

Almost any one, who for the first time follows the discussions on these subjects, encounters a little difficulty in the word *germ*, which is, perhaps, not a happy one to have come into use as expressing that from which a disease is derived. This, however, is its true meaning, and neither indicates a vegetable nor an animal character, nor even that it is living, though this latter notion is held by Beale.[1] For even should a disease-poison turn out to be a chemical substance, the term "germ" is equally applicable to it, according to the proper definition of the word. In fact, under this threefold character, we are called upon to study these active principles, for about these three possibilities, of a vegetable, an animal, or a chemical, character, are grouped the three prominent theories that have been framed to explain the origin of infective diseases. These theories, or hypotheses, as they might be more properly called, are (1) the vegetable-germ, (2) the bioplasm, and (3) the physico-chemical, theory. The infective diseases are such, in a general sense, as are either propagated by direct contact, or through the medium of the air, various gases, fluids, or common objects. Inquiries have mostly been directed to such of these as are called septic, viz., erysipelas, pyæmia, septicæmia, and puerperal fever, and to others known as contagious, miasmatic, and the like, such as smallpox and typhoid fever.

I shall try to sketch these theories briefly:—

I. The "vegetable-germ theory" is the one that heretofore has attracted more attention and interest than any other. Though we have known it under this name for only a comparatively short time, it is not of recent origin, and has in reality been recognized from very early times in the history of medicine. It was at first, of course, merely a hypothesis of the flimsiest character, though it soon came to be regarded as a possible one, when the microscope showed that both animal and vegetable organisms, of exceedingly minute size, lived and grew in the interior of the body.

More color was given to this theory by the labors of Schwann, Cagniard de Latour, and Kützing,[2] who found that in fermenting matters there was a growth and multiplication of minute organisms, which they regarded as vegetable; when at a later period Pasteur[3] asserted that these particles were conditions essential to fermentation, then it came to be assumed that the phenomena of disease, which in many respects resembled them, might be due to an analogous cause. It was in this way that the doctrine of vegetable germs as the cause of disease came to be regarded as having good *à priori* evidence in its favor. This belief was further strengthened by Schönlein, who, in 1838, published his account of the fungus plant found in Favus, which is now almost universally believed to be caused by the deposit and development of the plant in the diseased part. As further investigations were made, the silk-worm disease, and the potato-rot, or murrain, were also admitted to be caused by growths of a similar nature.

More recently it has been held that a great many of the infective dis-

[1] Disease-Germs, p. 10.
[2] Schützenberger on Fermentations, pp. 36–7.
[3] Bastian; Lancet, April 10, 1875, p. 502.

eases have each a microphyte,[1] or minute, microscopic plant, as its peculiar active principle. These latter alleged discoveries have, however, been received with marked opposition, many excellent authorities refusing to accept these matters as definitely proved.

II. Other hypotheses had, therefore, to be brought forward, and prominent among them was that of Beale,[2] who, admitting that particles of minute size may produce disease, and in fact laying stress upon this point, believes that the particles in question are degraded portions of the animal body. Such particles he tells us have been seen by him, when using a sufficiently powerful lens, and he assures us that they divide and subdivide under suitable conditions, and "as living matters alone divide." Ross[3] has a modification of the same idea, and Hutchinson[4] states, with reference to certain diseases at least, such as gonorrhœa, purulent ophthalmia, erysipelas, and phagedæna, that they are due to the contagion of living cell-material, such as is called protoplasm, or bioplasm. These tenets, with more or less modification, are sustained by those who believe in the "bioplasm theory."

III. Bastian deserves to rank as the ablest exponent of the remaining theory, the "physico-chemical," or "physical." It is called a modification of Liebig's old theory, and, as now enunciated, holds that though minute organisms may act as ferments, they do so by virtue of chemical actions set up by them, while minute particles of the human body have almost an equal capacity for setting up diseased action under suitable circumstances. In either case, bacteria are apt to be engendered as correlative products.[5]

It will be noticed that two of these theories are based upon the belief that the origin of disease is due to minute particles, and that this belief does not militate against the third theory, and is admitted as possible by its advocates. This simplifies the matter before us very considerably, and enables us to state at once that these poisons are *particulate*, or certainly that they are apt to be bound up with particles.[6] I will merely add here that, in my experience, it may be possible that this has always been the case; some of the particles or molecules, may, of course, be almost immeasurably small.

We may get a good idea of the controversial points by considering first the arguments brought forward by those who support the vegetable-germ theory, and then the answers or explanations of its opponents.

(1) I have already stated that after the publication of Pasteur's brilliant experiments in relation to fermentation and putrefaction, they were regarded as affording good, *à priori* evidence of the truth of the doctrine now under consideration. But it must be remembered that, though sustained by the observations of many others, these views were strenuously opposed by Willis, Stahl, Liebig, and others, chiefly of the German school.[7] There is little doubt now that these latter were in a measure correct; in fact, Pasteur[8] has seen fit to modify some of his earlier statements, for he quite recently has said that both alcoholic fermentation and putrefaction may be initiated by the chemical processes

[6] There is excellent evidence of this in all the diseases which are alluded to in this paper.

[7] Schützenberger, p. 40.

[8] Lancet, April 10, 1875, p. 508; and Tribune Médicale, Avril 1, 1875, p. 321.

taking place in the tissue-elements of certain fruits and vegetables, independently of the minute organisms supposed to be necessary to the process. Similar statements had previously been made by MM. Le Chartier and Bellamy, who found that, in modified forms of fermentation, independent organisms were generally absent at first, though they often made their appearance afterwards. Among the late contributors to this subject is Dougall,[1] who tells us that he has produced putrefaction without bacteria, and has seen bacteria without putrefaction—in which latter statement he can doubtless find many to accord with him.

Hiller[2] has also made statements to the same effect, for, having injected fresh eggs with a fluid containing bacteria, but not putrid, the eggs remained unaffected, which showed that bacteria might be present without decomposition ensuing. These views have been further supported by Donné and Beauchamp.[3] They are interesting, as showing that there has been, and still is, a diversity of opinion among scientific men as to the *rôle* which organisms play in fermentation and putrefaction. I may here add, also, that, in regard to the question of the ferment or cause of the ammoniacal decomposition of the urine, or fermentation, as it has been called, Pasteur[4] has stated definitely that it has not yet been demonstrated mathematically that the little torula to which he called attention several years ago, is the *cause* of the change, though he asserts that whenever putrid urine is examined the little plant is found.

(2) Another argument, commonly urged by those who believe in the vegetable-germ theory, is as follows: Almost all authorities admit that minute organisms may be the sole and sufficient cause of diseases such as scabies, favus, and the like, while many epidemic diseases among plants and animals are similarly produced, so that it is reasonable to suppose that vegetable organisms may be concerned in the production of infective diseases, the origin and propagation of which are thus explained with comparative ease. In reply, it is to be said that while no one may be willing to deny these facts, and while the silk-worm disease and potato-rot may be due to the vegetable particles that have been described; while various cereals may be affected with peculiar diseases, each exhibiting a peculiar plant; and while the pollen of many grasses may be the real cause of the hay-catarrh, or fever, as maintained by Blackley,[5] yet, that, on the other hand, it is certain that close observation in certain other directions shows the number of diseases due to vegetable growths to be really smaller than was formerly supposed. One has but to compare the long series of skin-diseases which but a short time ago were put down as caused by microphytes, with the modest list of five possible and three probable organisms, which are mentioned by a recent authority in these matters.[6] I refer to the Achorion of Favus, the Tricophyton of Tinea, and the Microsporon of Pityriasis versicolor.

The recent investigations of Lewis and Cunningham point in the same direction. They make it appear probable that in the Fungus-foot of India, the peculiar growth called Mycetoma is not necessary to the disease, as in some instances it has not been found, though the examinations were doubtless conducted with skill and care.[7] In the light of these and similar experiences, it would appear that while we are now and then dis-

[7] Lancet. January 22, 1876.

covering new plants or animals that act as disease-agents, we at the same time sometimes find that the number of such alleged causes of disease has been too large.

(3) It is further said that, in a number of the infective diseases, such as smallpox, typhoid fever, etc., there is a constant ratio between the intensity of the disease, in a given part, and the presence of bacteria; so that, where the disease is most active, bacteria are most numerous. This, indeed, is just what we should expect, in support of the vegetable-germ theory, and it is a fact that few of its opponents are prepared to deny. But it has long ago been shown by Schwann and others,[1] and more recently by Tyndall,[2] that the air at times swarms with bacteria; and it is also true that bacteria occur in the body in health, the mucous membrane of the alimentary canal, from the mouth to the anus, having been found peopled by myriads of them in active, independent motion.[3] These facts have been so generally confirmed, that, as it may be remembered, I assumed them at the outset. Now bacteria are also found in the heart of the tissues, which is explained by the fact that they are taken up by the absorbents, and carried about, while they have, in a certain number of instances, been found in the blood of the lower animals, and sometimes in human blood.[4] Now, as long as this remains true, it is for those who maintain this theory to show that there is a manifest difference between the bacteria which they believe to be disease-agents, and those that we know are generally to be found in the tissues; for the mere fact that bacteria are found in extraordinary quantity at any one point, does not by any means indicate disease. In a large number of experiments, performed by Dr. Curtis and myself, it was found that, under certain circumstances not incompatible with ordinarily good health, vast collections of bacteria were to be found upon the tongue. Under these circumstances, it seems to me perfectly proper to believe that bacteria occur in the diseases just named as correlative products, and not as causes, of the disease. I may here venture to state that, as far as diphtheria is concerned, and upon this matter I have made some special study, I have never found any organisms connected with the disease that could in any way be distinguished from those found at other times in the body.[5] Of these experiments, I shall say more presently.

(4) Now, while it is further alleged that, in another class of diseases, such as erysipelas and pyæmia, septicæmia, puerperal fever, and hospital gangrene, there is always a numerical increase of bacteria at the points involved, we may be allowed to state, in this case also, that, the presence of bacteria in the body being allowed, their tendency to accumulate in diseased portions does not necessarily show that they have any relation with the cause of the disease; and when the question is further asked, how may we distinguish the bacteria of such diseases from each other, or from those of putrid infusions, I think that the same difficulty will be found as in the case of the other infective diseases, before mentioned.

(5) An important question is often asked, viz., Can any strictly chemical substance be a fever-producer, or do we know of any substance, whose chemical nature we can express by symbols, that can produce fever? This is a question usually put to those who advocate the physico-chemical

[1] Beale and Sanderson.
[2] Lancet, May 8, 1875.
[3] Bastian, however, seems inclined to believe that these organisms do not come from the air.

[5] See Report on the Pathology of Diphtheria, in Report of the Board of Health of the City of New York, for 1877.

theory of disease. It may be impossible to answer it affirmatively, and yet this by no means settles the matter. The minute chemistry of animal poisons is far from being as yet in a satisfactory condition, but we cannot therefore say that such substances may not at some time be found. Weir Mitchell,[1] of Philadelphia, in his most extensive researches on the poison of the rattlesnake, assures us that the poison is an albuminoid body (which he calls *crotaline*), which is not precipitated by boiling, but is by alcohol. Prince Bonaparte seems to have found, also, that the venom of the viper contains a similar, albuminoid substance, which he has called *echidnine*. Hiller[2] also believes that, in glycerine, he has found a material that has the power of extracting certain chemical poisons in putrid and septic matters. We see, therefore, that a certain definiteness has been reached in our estimation of a few active principles, and it is possible that when this field has been more actively worked by the chemist, we may find those other matters which the microscope has failed to analyze, and which yet may react in a definite way, so as to show individual characteristics. It is also reasonable to suppose that chemical combinations of more or less complexity may be formed in the body, under the influence of peculiar processes, or of the presence of virulent matter, and then, in either case, may communicate like qualities to other ordinary matter of the body; for the venom of serpents is certainly formed out of the normal tissue-elements. In the case of chemical compounds, they may increase to an indefinite amount when placed in suitable liquids, where the proper constituents are present.

(6) It is also maintained, by the vegetable-germ theorists, that the extraordinary capacity which disease-poisons have of retaining their vitality, is a strong argument in favor of their being bacteria, which resist various reagents, and exposure to extreme degrees of heat and cold, and which may remain dormant for long periods of time, without losing their capacity for reproduction. It is known, however, that the poison of the rattlesnake resists boiling, and is not rendered less virulent by alcohol; and Fayrer[3] has asserted that this latter quality belongs to the poison of the cobra; but both boiling and alcohol prevent the multiplication of bacteria, according to the testimony of so large a majority of observers that this point has seemed to me sufficiently settled. Whether or not minute particles of human tissue are capable of living long after separation from the body, is still a question before us, and not one that can just yet be summarily dismissed, as some would imply.[4] But if it should prove true that the little particles of living matter soon lose their capacity for reproduction, it does not follow that they have lost their power of acting in such a way as to communicate qualities to, or set up actions in, other particles. This is advocated by one who believes in the physico-chemical theory.

(7) Again, it is frequently urged by those who believe in the vegetable-germ theory, that the bacteria of certain diseases will induce like diseases in other persons or animals, when inoculated. This may be true in the case of individuals, though there is testimony against, as well as for, this assertion.[5]

I may here state that the results of my experiments and of those of Dr. Curtis, in regard to diphtheria, have failed to show that the inoculation of the bacteria of diphtheritic membranes upon *animals* produce any

[4] Sanderson.
[5] Compare the statements of Wolff, Küssner, and others.

other lesions than those of bacteria artificially reared or obtained from our own mouths. Hiller[1] proposed to himself the following questions: whether (1) bacteria had the property of exciting inflammation, when inoculated? or (2) if in the blood did they produce fever? or (3) multiply? or (4) have the capacity of penetrating living organisms? He experimented on animals, using the bacteria taken from different kinds of decomposing substances. The temperature rose, but not above 2° Fahr.; on the third day, the bacteria at the point of inoculation were shrivelled, and on the eighth day they had disappeared. Even when introduced into the living blood, they soon ceased to be recognized, though in blood exposed to the air they multiplied rapidly. In this connection, the experiment which Hiller made upon himself, the results of which he exhibited at last year's meeting of the German Surgical Society, deserves more than a passing notice.[2] He allowed himself to be punctured in eight places with bacteria, which he had isolated by a method of his own. When these punctures were exhibited at the Congress, six days afterwards, they had nearly healed, no traces of redness, inflammation, or pustule, remaining. He also showed another place where he had been subcutaneously inoculated three days before with a fluid containing bacteria. There had been local œdema, occurring six hours afterwards, but it had disappeared in forty-eight hours, and on the day in which he made his communication to the Society his general condition was excellent, his appetite was good, and he had no fever.

My own experiments on animals agree in a certain number of instances with those of Hiller. When the bacteria were filtered out of Cohn's nutrient fluid,[3] in which they are known to grow with exceeding rapidity, and were inoculated in the thighs of rabbits, the organisms ceased to be visible after the fourteenth day, though there was usually a marked deposit of a pasty material at the point of inoculation. The same thing was observed when inoculations were made with tongue-scrapings, or with diphtheritic membrane; the bacteria soon ceased to multiply, though the time at which the process stopped was variable; they became bloated and distorted, so that it was hard to make them out; after three weeks, they were rarely seen at all, though the focus of disease remained extensive, the animals quite often dying at a later date with symptoms of constitutional infection. Still, in all of these experiments it is not probable that the bacteria were ever completely isolated, for even when Cohn's fluid was used, where the only organic substance was the tartrate, fermentation took place, and some of the products of fermentation, perhaps in the form of minute particles, may have attached themselves to the bacteria which then may have been *carriers* of the poison—itself a chemical product. And yet I have, in repeated instances, seen fluids inoculated upon rabbits, where the microscope showed bacteria in considerable numbers, though no trace of a lesion was observed.

We have now to consider a topic of great importance to us, in further defining our subject, and this is the classification of the organisms that are now called bacteria, to which class the vegetable-germ theorists, almost without exception, refer the agency of disease. Their name does not by any means imply that they are all rod-shaped, though the word *bacterium* means a little rod, but rather that they belong to a class of which

[1] Allg. med. central Ztg., 1, 2, 1874. [2] Archiv f. klin. Chirurgie, 1875.

[3] Tartrate of ammonium, 1 gramme; phosphate of potassium, sulphate of magnesium, each, 5 decigrammes; phosphate of calcium, 5 centigrammes; distilled water, 100 cubic centimetres.

the rod-shaped bodies are common types. Various classifications have been given of them, those of Billroth and Cohn having met with special favor, and each of these being tolerably complete. I will venture to say, however, that no elaborate classification appears to be necessary for these bodies, judging at least from our present knowledge of them, so that I shall describe them by common terms, which can be as well understood by those who are not familiar with these matters as by those who have carefully studied them. Simple as the classification will be, it is perhaps convenient rather than accurate, for while it seems to me to cover the whole ground, it may be questioned whether it does not do more; *i. e.*, give a reality to some forms the existence of which is in doubt.

First we have (*a*) the very minute, round bodies, varying in size from those which are described as having a diameter so small that they can barely be seen by the ordinary high powers of the microscope, up to those which have a diameter of about $\frac{1}{27000}$ of an inch; these are the Micrococci of Cohn, and the Microbacteria of Billroth; then we have (*b*) the little, oblong, or slightly oval, bodies that have a length of about one-third the diameter of a lymphoid corpuscle, and a breadth of about $\frac{1}{27000}$ of an inch; they occur singly, or in chains of two or more elements; thirdly, there are (*c*) the little chains which often appear to be made up of minute spheroids; fourthly (*d*), the globular masses that appear to be made up of spherical bodies (Zoogloea of Cohn, Colonies of Hallier, Gliacoccos of Billroth); and fifthly (*e*), the filamentous bodies which are so often seen to glide about with an undulating or serpentine movement across the field of the microscope (Spirilla of Cohn).

I use the term bacteria for all these forms, and yet, as I have already said, objection may be made to this classification. It is held by some that the round particles known as micrococci, are nothing but either the rod-bacteria, seen end-wise, or merely particles of dead granular matter, or perhaps particles from the living protoplasm of cells. It is probably true that many mistakes of this kind have been made, and yet I should feel disinclined to believe that there are no round bacterial bodies, coming within the range already given, for it has seemed to me that the chains just described are composed of minute spheroids. As for the filamentous bodies known as spirilla, they are also thought by some to be composed of spheres. These bodies when single, or in segments, have two states, one of activity and one of rest; but mere absence of motion does not necessarily indicate that they have ceased to live, for under changed conditions they again resume their motions and multiply. All small spheroids have a motion within a limited area, but it is difficult, if not impossible, to distinguish in them that motion which is called "independent"—which is inherent in them as living particles, and is not caused by external circumstances. It has long been known that the mere fact of motion, in such particles, does not indicate life; for all particles are apt to show a kind of motion, which is greater in very fluid media, and less in dense media. These well-known facts, however, do not seem to be sufficiently prominent in the minds of some who have written on these subjects.

Real motion in such bodies may be certainly recognized, when they move against or across currents, and do not merely show irregular rotation or vibration in a limited area. The rod-bacteria, chains, and long filaments, or spirilla, just described, have clearly this sort of motion, under certain conditions of life. The spirilla often dart across the field of the microscope, stop suddenly, and then dart back, or off in some new direction. Various micro-chemical methods have been devised for assist-

ing the eye in detecting them. Among those that have claimed the most attention, are the methods of Letzerich, Eberth, and Hiller, all of which are more or less useful. Letzerich[1] employs a watery solution of iodine, which imparts to the rods and chains a deep-brown color; but Hiller has shown that this method is unreliable, from the fact that granular iodine is deposited, and that there are no means, *probably*, of distinguishing the iodine particles from the so-called spherical bacteria, or micrococci, etc., if such be present. The mere size of such atoms gives no criterion for determining their character, for, according to Cohn, the distinguished botanist, they vary in size within exceedingly wide limits. My own experience in using this method has inclined me to coincide entirely with Hiller.

Eberth's test consists in boiling the suspected bodies in alcohol, or in caustic alkalies, by which process the rods, chains, etc., are unaffected; but this method is objectionable from the fact that if we wish to get rid of all the oil, which resists these reagents a long while, the suspected tissue is itself apt to be destroyed.

The best method, in my experience, has been that of Hiller.[2] I have found the following modification of it to answer well: Make a ten per cent. watery solution of caustic potassa, in which the tissue to be examined is then immersed for an hour and a half, then washed in distilled water, and finally plunged into a mixture of tincture of iodine and distilled water, 1–25; after remaining in this menstruum for fifteen minutes, the substance assumes a brownish or deep-yellow color. The fatty matters are more or less dissolved, excepting, in some cases, the larger oil drops, but the bacteria retain the color more or less deeply. Such of the round, oily particles as remain after this treatment, can usually be distinguished from bacteria, by the fact that they refract the light strongly, while bacteria have a dull, lack-lustre appearance.

Sometimes we are called upon to decide as to the character of the dark substances that exist in cells, to determine whether they are bacteria or not. I at one time adopted a modification of this plan. In an instance where a rabbit had shown signs of constitutional disturbance after inoculation with putrid matter, I examined some of the blood on the second day after removal from the body, when bacteria were very plentiful, and when most of the white blood-corpuscles had disappeared, while those that remained were enlarged and granular. I added liquor sodæ in excess to a small amount of the blood, allowing it to act for one and a half hours. At that time the white corpuscles had swollen and were generally dissolved, liberating a large number of granules. Ten of these were kept in view, and moved about in all directions, turning and twisting; at one time they arranged themselves in a cluster, and then again separated, and formed a chain. During this time, the bacteria of rod-form had become more and more invisible; while these particular bodies, on the other hand, had become brighter and brighter. During all this time there was little or no change in a number of oil drops that were scattered about the field. Here, then, we have an instance of liquor sodæ having afforded us a means of differential diagnosis, in an optical manner, between bacterial bodies and certain particles that took the chain-form, and that came from the interior of white blood-corpuscles.

One of the most important reasons for putting little reliance on exact measurements as to the size and form of bacteria, is that these charac-

[1] Virchow's Archiv, lxii. 3, 1875.

[2] Virchow's Archiv, lxii., Jan. 1875.

teristics are probably apt to change under varying conditions. Bastian tells us that if we take an ordinary organic infusion, and expose it to a warm temperature, it will show rod-bacteria. If we add a drop of acetic acid, we will get bacteria of larger size; adding a few drops more, the changes take place less rapidly, and the organisms, instead of multiplying as they did before, now grow continuously into filaments. This ground is said to be held by Trécul,[1] of Paris, and is favored by Beale;[2] my own experience is not sufficient to justify me in forming an opinion on this point. I may here add one point, viz., that I have seen no reason to believe that there is anything like a genetical relation between bacteria and the mould or sugar fungus.

I have already stated that my experience agrees with that of Chauveau and Sanderson, that the virulent principle is *particulate*, in certain instances at any rate. It is quite clear that very virulent fluids may be rendered quite harmless by passing them through a clay filter; this I have had repeated opportunities for observing, as far as relates to inoculation with putrid infusions, or with diphtheritic matter; and yet when we come to the question, *are these poisonous particles bacteria?* we know that by successive filtrations, as through paper, where the bacteria of distinctive forms are separated and removed, the fluid may still be poisonous. Granules are often observed in such fluids; *are they spherical bacteria, or the spores of these or others?*

We must remember, however, that rod- and chain-bacteria may be introduced in large numbers into the system without producing any lesion. When they *appear* to have been isolated, as in Cohn's fluid, this, as I have stated, is perhaps really not the case, but some organic compound may have attached itself to the vegetations, and thus have conveyed the septic influence.

Various efforts have at times been made to determine whether or not the poisonous matter is albuminoid. Chauveau, Onimus,[3] and Sanderson,[4] have worked in this direction. Sanderson and Onimus tried dialysis, and Chauveau diffusion. The former, in investigating the cause of the cattle plague, passed the virulent fluids through parchment-paper; the dialysate was wholly harmless, while the liquid that did not pass was poisonous. As the question with Sanderson was whether the contagia were crystalline or colloid, he decided in favor of the latter possibility. Onimus concluded that the matters were albuminoid from experiments conducted in much the same method. But there were in both sets of experiments, possibilities of error, arising from the fact that it was not certain whether albuminoid substances did not actually pass through the membranes, which it is now known that they will do, when certain quantities of the phosphates or carbonates happen to be present.[5] It would, therefore, be erroneous to conclude that the poison remaining behind the filter was necessarily albuminoid, when it was uncertain whether the harmless filtrate did not also contain albumen.

Chauveau appears to have shown, by his experiments, that it is extremely unlikely that the poison in vaccine virus is due to a soluble, albuminoid substance. His method will be briefly noticed. He took vaccine lymph, collected from the arm, and placed it in a test-tube standing in an upright position. The introduction of the lymph into

[1] Lancet, May 15, 1875, p. 684.
[2] Disease Germs, p. 37.
[3] London Medical Record, November 19, 1873.
[4] Twelfth Report of the Medical Officer of the Privy Council, 1869, p. 233.
[5] Graham, Proc. Royal Society, 1861, vol. ii. p. 243. I have not been able to refer to this paper.

the test-tube was effected with such care that the liquid did not touch the sides of the glass in the act of filling. Water, to the depth of a few lines, was then added with similar precautions, and the whole was allowed to stand for twenty-four hours. Although no membrane was used, yet it is said that when proper care was exercised, the liquids did not mix, except in the immediate neighborhood of the surface of junction. All the soluble constituents of the vaccine matter passed upwards into the water. At the end of twenty-four hours, the most superficial layer was removed by dipping into it the end of a fine capillary tube. This supernatant liquid was then examined microscopically, and tested for albumen. Now albumen, though held to have the least diffusibility of chemical compounds, was found in the water, the inference being that no other soluble chemical matter had been left behind. This upper stratum was used upon heifers and children, but without success, while the lower stratum produced the vaccine disease. Chauveau had previously employed a method called *subsidence*, in which, by adding ten volumes of water, he had found that the leucocytes were separated. These did not produce the disease, but the stratum that produced infection contained minute, microscopic granules, and it was therefore concluded that the disease was produced by them. Sanderson corroborated these conclusions in the great majority of his attempts, though he experienced some difficulty in the required manipulations, which need a good deal of delicacy.

Colin[1] asserts that he has been unable to "diffuse," as Chauveau claims to have done, and intimates that the method is faulty, and that no such real diffusion takes place; Chauveau, however, insists that the granules, even when washed with immense quantities of water, retain their virulent quality, and compares them in this respect to the spermatic elements of seminal fluid. The supernatant liquid which is not poisonous, responds to the test for albumen by heat and nitric acid. In farcy, Chauveau finds that the granules are as poisonous as the pus itself. According to Panum's[2] experiments, the virulent substance of putrid infusions is not destroyed by boiling, and is soluble in water, but not in alcohol; which qualities make him surmise that it may arise from the decomposition of albumen, or may perhaps be secreted from the bacteria, though he feels uncertain as to what the nature of the poison really is.

In prosecuting this line of inquiry, I have performed a number of experiments in co-operation with Dr. Edward Curtis, Professor of Materia Medica in the College of Physicans and Surgeons, New York, whose name I have previously mentioned in connection with other topics. The following questions were some of those that presented themselves for solution:—(1) Is the poisonous matter in putrid infusions destroyed by boiling and evaporation to dryness? (2) Is it soluble in alcohol, or not? (3) Is it soluble in water, after boiling in water and in absolute alcohol? (4) If there are granules in the fluid which prove poisonous, will they breed bacteria?

The liquid employed in these experiments was obtained from an infusion of a calf's liver, that had been allowed to become putrid; the liquids and solids used, were inserted into the muscular tissue of rabbits, and examined at varying times thereafter.[3] The following conclusions seemed in my opinion to be warranted:—

[1] La France Médicale, Fév. 26, 1876. [2] Virchow's Archiv, lx. 3 and 4, 1874.

[3] Many of these experiments have already been reported. In fact, this entire paper embodies views which were published in 1875. Medical Record, Dec. 18 and 25, 1875.

(1) Putrid matter, when introduced into the system, is capable of producing a well-marked train of symptoms, which are extraordinarily like those of ordinary *sepsis*.

(2) The poisonous quality does not reside in the absolutely clear liquid, when entirely freed from granules. This was shown by porous clay. The apparatus used in these experiments was devised by Dr. Curtis, and consisted of a porous-clay cylinder or cup, over the bottom of which was drawn a bit of rubber tubing, which was thick, and made to grasp the cylinder firmly; in the opposite end of this tubing was fitted a cork, through which a glass tube passed, so as to connect the chamber beneath the cylinder with the interior of a small glass jar that could be exhausted of air by means of a common exhausting syringe. When the liquid to be filtered was placed in the porous cylinder, and the air was removed from the glass jar, the liquid passed through the cylinder, and stood in beads or drops on its bottom, from which it was collected in small quantity without much difficulty.

(3) The poison is sometimes separated by coarse methods of filtration, such as by common filtering paper. When Cohn's fluid was passed through the equivalent of 25 thicknesses of ordinary filtering paper, it produced no lesion, and yet Cohn's fluid, unfiltered, and ordinary putrid infusions, produced about the same lesion.

(4) Continued boiling and evaporation to dryness does not destroy the poison.

(5) Continued boiling, and evaporation to dryness, and boiling with absolute alcohol, does not destroy the poison.

(6) The dry alcoholic extract, freed from alcohol by evaporation with heat, is poisonous.

(7) My experience with regard to the albuminoid character of the poison, has not made the matter clear to me, for while in these cases the dry alcoholic precipitate, after continued boiling, was poisonous (and it contained the albuminoid substances), yet the liquid alcoholic extract in one case produced a lesion, and in another did not. In my first account of these experiments,[1] the results were stated as above, but in a subsequent series of experiments, the liquid alcoholic extract produced extensive lesions in two cases in which it was tried. In other words, when the albuminoid deposit produced by both boiling and alcohol was separated, and water afterwards added, the virulent matter appeared to reside both in the precipitate and supernatant fluid. These experiments do not, therefore, decide anything as to the albuminoid character of the poison.

(8) It further seemed to be shown of putrid matters which, after being filtered several times, were boiled to dryness, then boiled with absolute alcohol, and again dried and extracted with water, that the ordinary paper filtrate was poisonous.

(9) On examining this watery liquid, it was found to contain granules, and yet, when these granules were placed in *vacuum-tubes*, they in several instances failed to show any development of bacteria under such circumstances as favored the growth of bacteria. The suspected solution was put away in bent tubes, with suitable precautions, and while similarly arranged tubes that had been contaminated with the barest trace of bacteria, were found turbid from the production of these bodies seventy-two hours afterwards, the suspected liquids were perfectly clear, with one exception, where there was a slight pellicle on the surface. It is true

[1] Loc. cit.

that, after a variable time, several tubes became contaminated, and yet others remained clear for months, and one for nearly a year, and as length of nozzle and fineness of neck are necessary conditions for success in the experiment, and as those thus provided held out best, it is fair to suppose that with the others some error was committed in carrying out the experiment, and that thus the bacteria of the air had in some way gained an entrance. That this is possible we have already seen.

It is proper now to stop here, and note that the granules have been very frequently noticed in the poisons of infectious disease; they seem destined to play an important part in the discussions now pending on the subject. There can be no question that in most of the diseases that are assumed to have a definite vegetable form as their immediate cause (for this is certainly the way in which the relation has been stated over and over again by the vegetable-germ theorists), authors have given the most conflicting accounts of the organisms, and we may fairly say that, with the exception of relapsing fever, not a single form has been accepted by any considerable number of germ-theorists as the agent, *par excellence*, of the disease. We have observed that, according to Chauveau, Sanderson, and Beale, certain granules appear to be associated with the origin of disease, and that this fact has been the point of departure of both the vegetable-germ theorists and the bioplasm theorists, while it is not incompatible with the physico-chemical theory. Let us examine these points a little more closely.

It is clear that if the vacuum-tube experiments be of value, they show that the particles observed are not the spores of bacteria. What evidence is there that the matter in question is organic and pertaining to the body? It is quite clear that, to the eye, using the ordinary powers of the microscope, these particles cannot be distinguished from one another with certainty. Beale,[1] however, assures us that by using extremely high powers, such as the $\frac{1}{25}$ or the $\frac{1}{50}$, he has seen them at times dividing, and at others increasing in size, and that he has colored them with carmine. Some of these may, he says, be no more than $\frac{1}{100000}$ of an inch in diameter. In diseased conditions of the body, he believes that such particles may increase enormously. Belief in this doctrine is, of course, inconsistent with the old cell-doctrine, by which this body was regarded as the ultimate morphological element of the system; and yet we may safely say that this old theory is not by any means what Schleiden and Schwann once held.

It does not appear to be necessary that a cell should have an enveloping wall, inclosing a softer material in which is a nucleus. Max Schultze showed that many important cells possessed no cell-wall, and that some might not have a nucleus. Our notions, therefore, have been greatly modified in these respects, and a living cell is now held to be merely a mass of glutinous, viscid matter, which is endowed with peculiar qualities, called vital, such as amœboid motion, molecular motion, and the like. As to the nature of this viscid substance, there is hardly much uniformity of opinion, as yet; some holding it to be formless and structureless, while others believe that it consists of networks, and others again, as Beale, that it is made up of minute spheres, closely packed together, and that these spheres may in turn be made up of other spheres. I hardly think, however, that microscopists are ready to agree upon any staining matter that is fitted to distinguish protoplasm or bioplasm in all cases, and these

[1] Disease Germs, p. 246.

statements of Beale must, therefore, be accepted with caution. Even if the particles be large, it is not certain that carmine will differentiate them. It has, to be sure, a preference for animal tissues, and yet it will also stain various other substances, if they remain long enough in the staining fluids. While, therefore, it is conceivable that the ultimate living elements of the body reside in particles which go to make up cells, we have no sure means of recognizing them, and of deciding positively that they are animal, and not vegetable, or whether or not they belong to that ill-defined class called granular matter. If, however, we believe that such minute portions of the body are the agents of disease, then we have to assume that they have a capacity for life which is remarkable: that, in fact, they can be subjected to extremes of heat and cold, or to the action of various acids and alkalies, and that they can be separated for months, and perhaps years, from the body, without losing their active qualities—all of which does not comport with the opinions commonly held about living animal matter.

The name "physico-chemical," as applied to the theory which is thus designated, is objectionable, as it dates back to the old-fashioned notions of Liebig, when the ideas held on these and kindred subjects were quite different from those of the present day. Liebig[1] held that the ferment was a portion of organic matter, which, itself unstable, was capable of communicating molecular movement (chemical change) to certain substances. Bastian, the exponent of the modified doctrine, holds, as already stated, that "living organisms, though they may act as ferments, act in this capacity merely by virtue of the chemical changes which the carrying away their growth necessitates, and that other chemical changes, taking place during the decay of organic matter, may make fragments of it (in the dead state) almost equally capable of initiating fermentative changes in suitable media."

This statement would appear to show that the friends of the theory are not altogether willing to deny to bacteria and allied forms, an influence in the cause of disease, but that they regard them as perhaps remote factors, the important one being the chemical change exerted by the growth of the microphytes, while, at the same time, dead organic matter may have a similar power. This theory is, therefore, properly a chemical one, and admits of two possibilities; either, on the one hand, that the cause of disease operates through chemical changes under the influence of minute organisms, or on the other hand, that it so operates under the influence of dead portions of the body. The former hypothesis is unlikely, because the virulence of diseases can sometimes be shown to be independent of bacteria; the latter one, however, is by no means impossible, though we know but little in its favor. If we assume that there is a logical connection between the processes of fermentation and disease, and decline to accept the hypothesis that minute organisms have that absolute *rôle* that has been given them, we may believe, with Hiller and others, that the ferment is a chemical substance. This is the view held by Bert with relation to vaccine virus, which he subjected to conditions under which life appeared to be impossible.

Under such an hypothesis, there is formed in the tissues, in certain diseases, a material which is able to resist various reagents (heat and cold, and the like), and which, when transferred to another organism, may occasion the formation of like compounds, just as the sulphate of sodium, instanced by Bastian, when placed in a liquid having the necessary ingredients for

[1] Lancet, April 10, 1875.

forming it, will increase in amount.[1] Now we actually know that the poisons of the cobra and of the rattlesnake, which are elaborated from healthy tissues, are capable of being subjected to conditions that are incompatible with life in its common acceptance. The poison of the cobra may be diluted with water, ammonia, or alcohol, without having its deadly qualities affected, while, according to Weir Mitchell,[2] the poison of the rattlesnake can be boiled or frozen, or subjected to the action of strong sulphuric or muriatic acid, ammonia, chlorine water, iodine, soda or potassa, and yet, as far as the matter has not burned, its virulence be unaffected. These qualities remind one strongly of the poison in putrid matters, where, according to my own and Panum's experiments, neither ordinary boiling in water, nor in absolute alcohol, nor evaporation to dryness, destroys its active qualities.

Let us glance, in conclusion, at the leading opinions at present entertained in regard to those of the infective diseases that have been most thoroughly studied with reference to the materies morbi. I shall refer merely to cholera, vaccinia, the carbuncular diseases of man and animals, typhoid and relapsing fevers, and diphtheria, in regard to which the most specific descriptions have been furnished of the organisms supposed to be concerned in their production.

The investigations which were occasioned by the *cholera* epidemic of 1849, appear to have been the first in which attention was called to certain particles, alleged to be the cause of the disease. These particles were called the cholera-fungus.[3] In 1867, Hallier[4] published a work in which he described the supposed ferment, the cholera micrococcus, a granular mass that by cultivation underwent a great variety of changes in form. Cohn[5] and many others followed with descriptions of the fungus. It is safe to say, however, that there has been no general agreement between the most prominent writers on this subject as to the specific form of the supposed contagium. In the Congressional report of the epidemic of 1873, in the United States, we find it stated[6] that no microscopic changes peculiar to cholera were found in the discharges, though high powers of the microscope were used; this being in agreement with the statement of Macnamara, who used a one-seventieth inch lens. Molecular matter was always seen by these observers, and it is stated in the report that from this molecular matter in the vibrionic stage of decomposition, and not from the vibriones themselves, the dejecta of cholera patients are capable of setting up a morbid action in the intestinal canal of those who receive them.[7]

Among the most recent and complete experiments on this point are those of Lewis and Cunningham.[8] They injected 36 dogs, through the veins, with choleraic dejections. In 15 cases they obtained positive results: that is, death was evidently due to the matter injected. In 17 of the cases this matter had been kept for ten minutes at a temperature of 212° Fahr. In the remaining 19 cases it had not been exposed to heat. In the 17 cases the mortality was 47 per cent.; in the 19 others it was only 36 per cent. It was thus found that a continued temperature of 212° appeared to have no influence in abating the virulence of the matter, for, when it was boiled, the mortality was even a little greater than in the other cases. These observers also believed that bacteria could not

be the cause of cholera, and in fact they found similar forms in the lesions produced by inoculation of various other substances, such as solutions of ordinary fæces, or urine.[1]

About ten years ago, it was noticed that *vaccine* virus contained minute spheroids, and they were described in 1867–1868.[2] Cohn called them *Microsphæræ vacciniæ*, and described them as small, colorless cells, sometimes in rosary-like chains of eight or more links, and sometimes clustered together. Sanderson thought that they were "filamentous, not jointed, but branching, and giving off from their extremities microspheres or conidia, much after the fashion of the penicillium." Having been favored by Dr. F. P. Foster, Director of the Vaccine Department of the New York Dispensary, with an opportunity of inoculating calves, I performed the following experiment in relation to this matter. Having prepared a solution of salicylic acid, with sodium phosphate as a solvent, I combined it with equal parts of vaccine virus taken immediately from fresh vesicles, and having allowed the two to remain in contact a minute, they were inoculated in my presence, on a calf, in the usual way. Now this proportion of salicylic acid ($\frac{1}{500}$) had been shown by previous experiment to be able to prevent the development of bacteria for from twelve to twenty-five days, and yet in this instance regular vesicles appeared at the proper time in nearly all the inoculated points. I cannot but think, therefore, that this experiment offers strong evidence against the theory that vegetable germs have to do with the cause of disease.

The name *Carbuncular Diseases*, which the French employ synonymously with the German word Anthrax, has proved to be a convenient form for a rather remarkable group of contagious diseases, which have a certain connection with one another, and which include malignant pustule, splenic fever, and the disease called "mycosis intestinalis." The post-mortem appearances in all these diseases are remarkably similar. Balls of rounded particles are said to be found in the affected parts, and rod-shaped bacteria in the circulating blood; the spleen is enlarged; there are hemorrhagic infarctions of the intestine, causing sloughing of the mucous membrane, exudation and infiltration of serum, and enlargement of the glands near the points involved. In such cases a pustule often appears, and hence the name Malignant Pustule; and yet it may not be necessary to the disease, which often proves fatal without it. Now, in these diseases, Pollender and Davaine[3] observed minute rods, which Davaine called bacteridia, and which he said were always motionless; and he has made such extensive studies of them that his opinions have become well known. He regarded them as necessary causes of the diseases in question, and as essentially different from what he called the bacteridia of decomposition, which were really what we know as the bacteria of putrid matters. His views have, however, not always met with acceptance, and notably have been opposed by Bouley,[4] Gaillard, and others, who assert that the blood may be infectious without the presence of rods. Bodinger, who is now regarded as one of the foremost German authorities, states that he also has produced the disease in question in a similar way, but that in such cases there have always been spherical bacteria present. We may justly ask, in view of what has already been cited, whether spherical bacteria were really present, and whether the particles he describes may not have been other solid particles?

Among the most recent and best recorded accounts of the vegetable organisms connected with *typhoid fever*, are those of Klein,[1] of London. He declares that he has found peculiar bodies, in this disease, at or near Peyer's patches. These bodies were carried along the lymphatics or bloodvessels of the mucous membrane; in color they were often yellowish-brown, and in size varied from one-fourth to three times the size of a human, red blood-corpuscle. It will be noted that if we accept these views, we are carried away from the subject of bacteria towards that of the other vegetable organisms, called torulæ, which in my opinion have not been shown to have any genetical relation with bacteria. These views of Klein are comparatively new, and as yet I have failed to find any confirmation of them.

In regard to *relapsing fever*, the microphytes are pictured with more vividness than in any other disease. In 1872, Obermeier, of Berlin, gave an account of certain bodies, long and filamentous in form, which were found in the blood during the rise of the fever, disappearing with its fall, and reappearing during the relapse. These observations have been very largely confirmed, but, on the other hand, Laptschinski made frequent searches for these bodies, but never found them, though he did observe an enormous increase in the number of the white blood-corpuscles, which were unusually granular; when the fever decreased, the number of the white blood-corpuscles diminished. Recently, Heydenreich,[2] of Moscow, examined the blood in sixty-four cases, and he asserts that he found the spirillum in every instance, and that it was the same as the Spirochæte plicabilis, of Ehrenberg, which this observer discovered in water. In most cases these bacteria were found at the beginning of the febrile exacerbation, sometimes even preceding it. Before the fall of the temperature, the bacteria generally disappeared. On the other hand, we are told by Motschutkoffsky,[3] of Odessa, that the blood of relapsing-fever patients was readily and successfully inoculated upon healthy human subjects, though not on animals. The blood was only poisonous when it was taken during a febrile exacerbation, but it made no difference whether it contained spirilla or not.

In the matter of *diphtheria*, I may speak with more confidence, as my personal experience in this department of the subject is larger than in any other. The relation of bacteria to diphtheria has been made most prominent by the writings of Oertel, Hueter, and others; and, in conjunction with Dr. Edward Curtis, I have made some extended researches on the subject. Oertel, and others of the German school, plainly ascribe to the micrococcus found in diphtheria, the cause of the disease; at least I can understand them to imply nothing else. In the first instance, it must be said that the real presence of bacteria in diphtheritic membrane is usually a matter of ready proof. They exist in collections on the surface of the membrane, and often in it, as well as in the secretions of the pharynx, trachea, nasal passages, etc. They are to be found in masses, or separate, and usually may be distinguished as rod-shaped. It is true that they often appear as spheres, but this appearance is apt to be deceptive, for, when they are accumulated together, they are often arranged in extremely regular order, and they then give this peculiar appearance. To show that in such cases they are rods, is not a matter of much difficulty: Press the cover against the slide, and the

[1] Report of the Medical Officer of the Privy Council, 1875.
[2] St. Petersburger med. Wochenschrift, 1, 1876.
[3] Centralblatt, and St. Louis Medical and Surgical Journal, May, 1876.

more prominent rods will be pressed down, showing their peculiar shape. Another source of deception is the fact that these bacteria are apt to move about with a gyratory motion, with extremity directed towards the observer. Watching such a particle carefully, it may sometimes be seen to turn and expose its side, and then we may see that it is nothing but the ordinary rod-bacterium. When we have to do with other particles, then indeed it is well to give diagnostic points by which we may distinguish them from ordinary granular matter, such as fragments of tissue, minute oil particles, pigmentary matter, etc. I feel confident, however, from repeated examinations, that no particles have been described by Oertel as micrococci, that can be positively shown to be present in diphtheria alone. On the contrary, both Dr. Curtis and myself have repeatedly examined the accumulations in our own mouths, and have there seen the forms which are described as belonging to diphtheria.

And yet diphtheritic membrane is very poisonous, and fatal when inoculated in the muscles of rabbits, as I have had repeated opportunities of observing. I may here state that Oertel's descriptions are the most elaborate and, perhaps, the most clearly given of any writer's on the experimental pathology of diphtheria; as far, however, as my experience has gone, it has in most instances failed to verify them. In inoculating the corneæ of rabbits, in a number of instances, no lesion followed, beyond an ordinary keratitis, and none of the rabbits died; in fact they all recovered quickly. The fresh diphtheritic membrane, when inoculated, was very fatal, the tendency to death being extremely common about the end of the second day. Of 27 rabbits inoculated with the solid membrane, or an aqueous infusion of it, 20 died, and 12 at about the end of the second day, or between the second and third.

Now the membrane when thoroughly boiled, was equally fatal in two cases, and yet boiling is said by most excellent authorities to destroy bacteria. In fact, this is a matter of general belief. Furthermore, bacteria were shown to decrease rather than increase, when introduced into the system, so that certainly after two or three weeks they had either become distorted, so as to be hardly recognized, or they had altogether disappeared. When very strong solutions of salicylic acid, combined with phosphate of sodium as a solvent, were made up into a paste with diphtheritic membrane, and inoculated in the thighs of rabbits, they produced a fatal disease, though the lesions were not as extensive as when diphtheritic membrane alone was used; and yet, in my experience, salicylic acid in the proportion of $\frac{1}{500}$ has, as before mentioned, prevented the development of bacteria for from twelve to twenty-five days.

I believe that I have now given a tolerably fair account of the most prominent views entertained on the matter of disease-germs, and think that I am warranted in submitting the following conclusions with regard to the present status of the question:—

I. That, as far as inquiry has been made as to the nature of the active principles in infective diseases, it is probable that in a certain number the matter is particulate, or molecular in form.

II. That in regard to the causes of septicæmia, pyæmia, puerperal fever, erysipelas, and hospital gangrene, and those of cholera, vaccine-disease, the carbuncular diseases of men and animals, typhoid and relapsing fevers, and diphtheria, there is not satisfactory proof that they are necessarily connected with minute vegetable organisms.

III. That the real nature of these causes is still uncertain.

VITAL STATISTICS OF BUENOS AYRES.

BY

G. RAWSON, M.D.,

OF BUENOS AYRES.

A BRIEF review of the vital statistics of Buenos Ayres may perhaps awaken some interest in the International Medical Congress now assembled in Philadelphia, not only as adding to the data accumulated from day to day as elements of Sanitary Science, but as presenting circumstances peculiar to that Argentine city itself.

Buenos Ayres, next to Rio de Janeiro the most populous city in South America, has grown with extreme rapidity, having tripled its population within the last twenty-five years, mainly owing to the vast tide of emigration from European shores. But, even in the event of a diminution of the influx of immigrants, and a corresponding reduction of the rate of increase, it is almost certain that Buenos Ayres will, at the close of the present century, have upward of half a million inhabitants. Situated in latitude 35° south, with a genial climate, it is exempt from the extremes of temperature so common in other localities; and, were it not for the modifying influences exercised upon its sanitary condition by the increase of population, and by the circumstances usually attending that increase—when not overruled by strict observance of the admonitions of science—it would be as healthy a city as its name (*good air*) would seem to imply.

But the death-rate in Buenos Ayres attains proportions by no means satisfactory; and the recent epidemics, particularly the yellow-fever scourge of 1871, show that much has to be done before the city can regain that salubrity reasonably to be expected from its situation and soil, and from the prevailing winds and other climatic conditions with which it is favored by Nature. Epidemics are warnings to mankind—warnings all the louder in proportion to the severity of the visitation; and Buenos Ayres has learned from her recent sufferings the lesson to be desired. Works, both above and beneath the surface, are now in prosecution for the sanitary improvement of the city, by means of a system of drainage and underground disinfection which will cost twenty millions of dollars (eight millions have already been expended), and which, when completed, will be one of the most efficient in the world.

Besides, the population of the city is, to a great extent, composed of foreign elements permanently incorporated therein and constantly increasing. In this respect Buenos Ayres bears a striking analogy to many cities in the United States, and, like these, presents a series of phenomena peculiar to this species of social evolution, as revealed in its vital statistics. The analogy here referred to I shall endeavor to point out in the course of the present essay.

Population of Buenos Ayres.—It is necessary, first of all, to determine the population of Buenos Ayres, and its component elements; but the accurate accomplishment of this is difficult, owing to the long intervals between the censuses, and the rapid increase of the number of inhabi-

tants. The mode of development in cities of the New World is in general so irregular that, in measuring their growth, it will not suffice merely to determine the difference between the numbers of births and deaths. The increase resulting from that tardy process is insignificant when compared with that derived from immigration, and with that which is due to the irresistible attraction which populous centres exercise at all times upon neighboring towns. This species of attraction is, from causes peculiar to the Argentine Republic, more powerful in Buenos Ayres than in other American cities of similar growth. In 1871, for example, the number of victims of the disastrous yellow-fever epidemic exceeded that of the births in the same year by 13,206: but the equilibrium of the population was more than re-established by the influx of emigrants from Europe, and from the surrounding provinces and republics. By comparing the total number of births during the period from 1858 to 1872 with the total number of deaths during the same period, including, of course, the victims of the cholera of 1867 and 1868 and those of the yellow fever of 1871, we observe an excess in the deaths, of 1778. Hence, if Buenos Ayres had depended solely upon its own resources for its growth, its population, instead of increasing, would have diminished. But the ravages of this frightful mortality were more than compensated for by immigration, and the remarkable growth of the city pursued its course without any apparent interruption.

The progress becomes more and more marked, dating from 1852. In the absence of official data, it is scarcely possible to estimate the population of Buenos Ayres in that year, which was marked by a political event of transcendent importance—the downfall of the dictatorship by which the nation had been oppressed and depopulated for the space of twenty years. Numerous emigrants returning to their homes after a prolonged proscription; the establishment of liberty, political and civil; the opening the navigable rivers to the vessels of all nations; the discovery of riches susceptible of being developed advantageously in the Argentine Republic by the hand of man; and the facilities offered by both the government and the people to foreigners desiring to take up their residence there, induced a stream of European immigrants, which continued uninterruptedly for a number of years. Dating from the beginning of the influx of foreigners, the rapid growth of the population became evident, and about that time the greatest increase took place. Nevertheless, no census of the city was taken until 1855, nor was a second effected until 1869, the year of the general census of the republic. According to the terms of the constitution, the general census will in future be taken every ten years.

The two censuses referred to are, therefore, the only available data on which to base my computations; those for other years must, of necessity, be only approximate. In the census of 1855, the total population of the city was set down at 91,548, and in the general census of 1869, at 177,787. Hence, the mean annual rate of increase during the period embraced between these two extremes would be 4.8 per cent., always supposing the progression to have been uniform. Now, by applying the same system of reckoning to the previous years, that is to say, from 1852, and to the successive years down to 1875, the population of Buenos Ayres would be as in the annexed table in the years therein expressed:—

1851, by calculation	76,000	inhabitants.
1855, according to census	91,548	"
1869, " "	177,787	"
1875, by calculation	230,000	"

On reviewing the foregoing statement of the increase of the population, two objections are apparent, and I must now endeavor to explain them. They are: first, the epidemic of 1871, which would appear to have checked for the time being the numerical advancement of the population; and, second, the perceptibly decreased immigration in the last two years, 1874 and 1875.

Buenos Ayres is not only the chief port, but also, by reason of its position, the natural centre of all movement in the republic. It is the point of disembarkment for the immigrant on his arrival, and of re-embarkment for those who return to Europe. Passengers, whether immigrants or not, coming from Montevideo, likewise land at Buenos Ayres; and there they go on shipboard again when leaving to go back. There, too, is the rendezvous of all craft navigating the tributary streams of the Rio de la Plata. Hence, the movement of passengers throughout the year may at all times be readily ascertained, and the balance to the credit or debit of Buenos Ayres accurately determined by comparison of the arrivals and departures. The communications by land are extremely limited, and confined to the rural districts of Buenos Ayres and the neighboring provinces. It is generally admitted that more than two-thirds of all immigrants to the republic, come whence they may, remain in Buenos Ayres city, the remainder being distributed through the surrounding country. The following table shows the movement of passengers for the port of Buenos Ayres in the years 1864–72:—

Years.	Arrivals.	Departures.	Balance remaining.
1864	29,307	16,745	12,562
1865	30,556	24,434	6,132
1866	40,132	20,658	19,474
1867	42,729	21,154	21,575
1868	56,354	25,342	31,012
1869	73,045	29,990	43,055
1870	81,166	33,450	47,716
1871	49,741	28,468	21,273
1872	70,991	36,756	34,235

As seen in the foregoing table, in 1870, the year immediately following the general census, the balance in favor of the population reached the highest point so far known, as far as the arrival and departure of passengers were concerned. That year was an auspicious one for the city. Immediately after the termination of the Paraguayan war, a vast accumulation of capital was effected, credit facilities were opened up, encouragement was offered to such as desired to embark in new industrial enterprises, and important public works were undertaken, such, for instance, as city railroad lines: and the result of all these favorable circumstances was the attraction to, and permanent establishment in, Buenos Ayres, of a vast number of people from foreign countries and from the other provinces of the republic. The influx of strangers at that time amounted to two-thirds of the balance of 47,716 mentioned in the table, that is to say, over 30,000 new inhabitants, which is equivalent to three and one-fourth times the usual rate of increase. Such an excessive augmentation of numbers, at a time when the city was not suitably prepared to receive them, or to afford them necessary accommodation, gave rise to an accumulation altogether incompatible with the general good health, and contributed, beyond all doubt, to the awful severity of the epidemic of 1871, by which more than 12,000 foreigners were carried off.

The yellow fever committed its ravages in the midst of an overcrowded city. But, notwithstanding the great mortality, there still remained,

with a surplus for the following year, a mass of inhabitants greater than would have been obtained by calculation, adopting the established annual rate of increase, and to which should be added the number of the immigrants of 1871 who settled in the city. These remarks may serve to meet the first objection above alluded to.

As for the second, suffice it to state that, in 1872, the tide of immigration again began to flow, and foreigners arrived in such numbers as to leave a balance of 34,235; and that in 1873 immigration reached the highest figure ever attained in South America, leaving a balance much more favorable still than that of the year immediately preceding; I deeply regret that I have not at hand the official returns to offer in support of this statement. In 1874 and 1875, by local causes easily explained, and others of a general character which have produced and still produce such grave perturbation in commercial and industrial circles throughout the world, immigration to Buenos Ayres was considerably diminished, while emigration was increased in a proportionate degree. There has, nevertheless, been no instance as yet, even at the worst, of the departures having exceeded, or even equalled, the arrivals; a balance, however small, still exists in favor of the latter. Now, taking into consideration the excessive accumulation which occurred in the two years immediately preceding the crisis, the same reasoning may apply to 1874 and 1875 as we have already applied to 1871, with the favorable difference in the case of the two former years that they were marked by no such catastrophe as the epidemic of the latter, to exercise a depressing influence upon the population. Hence, the adoption here of the mean annual rate which served us in estimating the number of inhabitants for the earlier periods, would seem perfectly justifiable; and we may, without any fear of exaggeration, set down the population of Buenos Ayres in 1875 at 230,000.

This population is spread over an area of 1620 hectares (or 6 square miles approximately), or a mean of 70 square metres (= $83\frac{2}{3}$ square yards) to each individual. Of course, the distribution is not always uniform. There are many districts much more densely populated than others, and the tenement-houses, though disseminated through all the districts, are in themselves centres of accumulation, pernicious alike to the physical and moral well-being of the community. The streets are for the most part narrow, barely eleven metres in width; and the public squares are few and of inconsiderable dimensions. Within the last few years, a vast system of horse-railways has been introduced, with an aggregate length of seventy miles, by means of which cheap mode of conveyance a certain degree of expansion is afforded to the inhabitants. It may here be observed that, with the exception of Philadelphia, Buenos Ayres has, in proportion to its population, a greater extent of horse-car lines than any other city in the world.

From this short history of the development of the population of Buenos Ayres, it may be presumed that it is largely composed of foreign elements. Indeed, the census of 1869 shows that, in that year, foreigners constituted almost one-half of the total number of inhabitants.

Total population		177,787
Argentines	89,666	
Foreigners	88,121	
		177,787

Doubtless the proportion of foreigners has increased in a marked degree since that time, and, in the absence of precise data, I calculate that their number in 1875 exceeded that of the natives as follows:—

Total population	. . . .		230,000
Argentines	. . . . .	105,000	
Foreigners	. . . . .	125,000	
			230,000

But, in order to give an idea of this foreign mixture, and commence the study of the vital statistics upon a more solid basis, I shall here transcribe a page from the census returns of 1869, with all the details and particulars to which we may have occasion to refer.

Table showing the Population of the City of Buenos Ayres, in 1869, *Arranged according to Nationality, Age, and Sex.*

Attention is at once attracted by the numerical relation of the predominant elements in the native and foreign populations respectively. It should be borne in mind that, among immigrants to Buenos Ayres, the male element is far in excess of the female, and that for reasons as obvious as they are natural. The pioneers of emigration are always robust men in the prime of life; and not until prolonged experience has proved the certainty of happy results, do the women and families set out to share the fortunes of the fathers and brothers who have left their native homes. Immigration to the United States has now assumed a character of permanency and stability induced by satisfactory experiments extending over more than half a century; nor is it to be wondered at that immigrants arrive on the shores of the Union in a state of almost complete family organization, or, at least, that 45 per cent. of them are females of all ages. And it is a noteworthy fact that the distribution of female immigrants throughout the country is, according to the census of 1870, in direct ratio to the age of the States. In Maine, New York, and Massachusetts, for instance, the female foreign population is equal to, or often in excess of, the male; while in the new States and in the Territories, the number of females in the foreign population is small as compared to that of the males, save in the single Territory of Utah, where, for well-known reasons, the reverse is the rule.

The population of Buenos Ayres in 1869 comprised:—

Males of all ages and nationalities	98,091
Females " " "	79,696
Total	177,787

The Argentine branch of the population, of all ages, comprised, in the same year: males, 37,486; females, 52,175; or an excess of 14,689 females. In the foreign branch, including all ages and nationalities, there were: males, 60,605; females, 27,521; or an excess of 33,084 males, which not only compensated for the deficiency of males in the Argentine population, but constituted an excess of 18,395 males in the total number of inhabitants.

In regard to age, children under five years numbered 23,367, of whom 2290 had been born in foreign countries. In New York, the number of children of that age, so interesting in the study of vital statistics, is equal to 11.8 per cent. of the whole population, while in Buenos Ayres it constitutes only 13.1 per cent. From the age of five to fifteen, the proportion of foreign-born children gradually increases, which is likewise observed to be the case in New York, as shown by the report of the Commissioners of Emigration for 1875, in which children not over twelve years of age represented 21 per cent. of the 84,000 immigrants who arrived at that port in the year mentioned. The period ranging from sixteen to sixty years, is that in which the numerical superiority of the foreign population is most marked in Buenos Ayres; and the same phenomenon is observed in New York, though without the strange proportions characteristic of the former city. This is the period of life in which full physical and moral development are attained—plenitude of power for labor, for reproduction, and even for organic resistance of the permanent influences which menace health and existence. In this triple point of view, the foreign population is certainly superior wherever it presents, as it does in Buenos Ayres, such an evident majority of individuals in the age of vigor and strength.

Marriages.—The following table shows the number of marriages that took place in each of the seven years from 1867 to 1873. I have taken care to compare the numbers with the population in the respective years, calculating the latter according to the established rate of increase, in order to ascertain the number of persons per thousand married in each year:—

Years.	Marriages.	Number of persons married per 1000.
1867	1530	19.0
1868	1703	20.2
1869	1858	20.9
1870	1916	20.5
1871	1896	19.4
1872	2193	21.4
1873	2291	21.3
Mean number of persons married per 1000 during 7 years		20.39

From this table it appears that the number of marriages increased gradually, save in the year 1871, in which there was a decrease of 20 as compared with the figures of the year immediately preceding, due to the perturbation caused by the great epidemic. In the succeeding years the increase was again visible, as was also that of the population. It is likewise to be observed that the proportion per thousand varied very little, and may be set down at an average of 20, though the mean for the seven years was 20.39. Figures in statistics assume greater importance when compared with others of like nature. Here, as in other branches of the present report, I prefer to make the comparison with the city of New York, not only because I have ready access to the official documents relating to the vital statistics of that populous city, but also on account of a certain analogy which I find it to bear to Buenos Ayres in the department which now engages my attention. The number of marriages in New York in each of the same seven years, as given in the reports of vital statistics published by the Board of Health, and for which I am indebted to the courtesy of Dr. Nagle, will be seen in the subjoined table. I should add that, in computing the rate per 1000 of persons who

married, I have estimated the population before and after the census of 1870, according to the rate of increase—say 2.1 per cent.—adopted by the official authorities:—

Years.	Marriages.	Persons married per 1000.
1867	7144	16.14
1868	6926	15.33
1869	8695	18.44
1870	7985	14.71
1871	8646	18.07
1872	9008	18.52
1873	8887	17.72
Average		16.99

This mean annual rate may be regarded as somewhat below the truth for New York, inasmuch as the Registrar-General, in the course of his reports, complains of the culpable negligence of some of the persons required by law to have marriages registered in the proper office. At all events, the data I have adopted as the basis of my calculations are of official origin, and they show the increase in the number of marriages to be not uniform, as likewise the proportion per 1000. This variability or lack of uniformity I am at a loss to account for, nor am I aware to what causes, social or economical, it should be attributed. I shall add, by way of comparison, a list of the marriages in nine American cities in the year 1872, observing that the population of the city of New York has been increased in the proportion corresponding to two years after the census.

1872.

Cities.	Marriages.	Number per 1000 of persons married.
New York	9008	18.52
Boston	3762	28.38
Philadelphia	6496	19.28
Richmond	567	18.90
Providence	943	26.46
Pittsburg	1143	26.56
Albany	613	16.14
Newark	1241	23.62
Jersey City	677	15.74
Buenos Ayres	2193	21.04

In view of the heterogenous composition of the population, it is important in a statistical point of view to inquire into the nationality of the consorts. The results of observation in this respect are, in Buenos Ayres, as follows:—

Marriages according to the Nationality of the Consorts.

Year		Argentines.		Foreigners.
1869	Males	444	Males	1414
	Females	719	Females	1139
		1163		2553
1870	Males	519	Males	1397
	Females	770	Females	1146
		1289		2543
1871	Males	478	Males	1418
	Females	737	Females	1159
		1215		2577

1872	Males	485	Males	1708
	Females	722	Females	1471
		1207		3179
1873	Males	418	Males	1873
	Females	758	Females	1533
		1176		3406

In these five years, the number of foreigners who married is seen to exceed by far that of the Argentines. And if, for the sake of greater accuracy, we take the year 1869, bearing in mind that the foreign and the Argentine elements were then almost equal, the different nationality of the persons who married can only be explained by special comparison of the foreign element in relation to age and sex. Thus, the number of Argentines who contracted marriage in the year referred to was 1163, and that of the foreigners of both sexes, 2553—that is to say, about 2.19 of the latter to 1 of the former. It will also be noticed that the number of Argentine males was in still greater disproportion to that of the foreign males, namely 444 to 1414, or as 1 to 3.18. Still another comparison with one of the foreign nationalities: The Italian population is set down in the census at 41,957, against 89,661 Argentines. Now, the number of Italians who married in the course of that year reached 1304, and that of the Argentines 1163, of both sexes, while the Italian males amounted to 704, and the Argentines to only 444. A similar disproportion is noticed in New York in a series of years. Let us take, for example, the year 1873:—

Natives.		Foreigners.	
Males	2688	Males	6,183
Females	3530	Females	5,341
	6218		11,524

Here the natives stand in the proportion of 1 to 1.8 of both sexes, the proportion of native males being even smaller—1 to 2.3. The same observation may be made in New York with reference to the German nationality, as that I have just made with respect to the Italians in Buenos Ayres. The German population, according to the census, amounted to 151,216, the native having been 523,198. Meantime, while but 6218 native Americans of both sexes contracted matrimony, the number of Germans who married was 6340. And, in order to render the analogy still more marked, let us mention that the American males who entered into wedlock numbered only 2688, and the Germans 3416.

Births.—The same uniformity of progression appears in the births. It may also be stated with certainty that the number of births follows the increase of the population, preserving with it a uniform proportion, which proves that the registration has been carefully attended to, and that my estimate of the population before and after the census is neither excessive nor deficient. Although I have the registers from 1855 down to 1873, I only adopt in the following table those relating to the five years commencing with that of the census, and consequently including the unhappy year 1871:—

Years.	Population.	Births.	Rate per 1000.
1869	177,787	6944	39.3
1870	186,320	7561	40.5
1871	195,262	7549	38.6
1872	204,634	8078	39.4
1873	214,456	8559	39.9
Mean annual rate per 1000			39.5

Continuing the comparison with the vital movement in New York, I transcribe from the official documents the number of births during the same five years, in relation to the population calculated according to its annual growth:—

Years.	Births.	Rate per 1000.
1869	13,947	15.17
1870	14,524	15.41
1871	20,821	21.64
1872	22,068	22.45
1873	22,683	22.61
Mean annual rate per 1000		19.45

The different rates in the first two years as compared to the others may perhaps, in the absence of a visible specific cause, be attributed to a defective system for the registry of births. But, even taking the proportion of 22.61 per 1000, which is the maximum, it is far from the mean annual rate in Buenos Ayres. The accompanying table will show the proportion of births in a few cities of Europe and America, and will serve to demonstrate how variable that proportion is in different nations, though not on account of difference of race, but from other and complex causes which must, sooner or later, come within the range of sanitary science:—

Cities.	Births in 1873.	Rate per 1000.
Brussels	6,200	33.51
London	121,100	36.05
Bordeaux	5,036	25.95
Berlin	36,281	38.19
Dublin	9,031	28.70
Milan	9,091	33.52
Mexico	9,273	41.21
Boston	9,688	35.07
Brooklyn	5,027	11.54
Philadelphia	17,811	23.74
" (1874)	19,387	24.07
Chicago	9,718	24.29

In some American cities the proportion of births is so low, as observed by the Board of Health of Philadelphia in its reports, as only to be accounted for by defective registration. If such be the case, the necessity of reform is evident in this very important department of statistics.

The matrimonial statistics with respect to the nationality of the consorts, would seem to promise a like proportion in the births with respect to the nationality of the parents. I shall confine my examples in the following tables to births of children whose parents were either both Argentines or both foreigners, omitting cases of parents of mixed nationalities, and cases without any specification.

	Births.		
Years.	Parents both Argentines.	Parents both foreigners.	Proportion.
1869	1512	3314	1 to 2.0
1870	1403	3881	1 " 2.7
1871	1564	4019	1 " 2.4
1872	1580	4451	1 " 2.8
1873	1543	4738	1 " 3.0

The proportion of children of foreign parents to children of Argentine parents, increased from 2 to 1 in 1869 to 3 to 1 in 1873, it being worthy of remark that the augmentation coincided with the most extensive immigration. Here, again, I meet the same analogies as before between Buenos Ayres and New York, as set forth in the subjoined table, in which

are included only births of children of American parents and children of foreign parents.

Years.	Births. American parents.	Births. Foreign parents.	Proportion.
1869	2457	9,080	1 to 3.7
1870	2553	9,282	1 " 3.6
1871	2631	14,144	1 " 3.8
1872	3721	14,829	1 " 3.9
1873	3827	15,353	1 " 4.0

In New York, the excess of births of children of foreign parents, as compared with those of children of American parents, is more remarkable, inasmuch as it reached the proportion of 4 to 1 in 1873. This extraordinary proportion is far in excess of that suggested by the number of marriages according to nationalities, and indicates that the fecundity of these different classes of persons is affected by other causes, as proved by the two following facts: (1) That the predominance of males over females is greater among children of foreign than among those of American parents, and (2) That, according to the curious observations contained in the tables of statistics published by the New York Board of Health from 1870 to 1873, among American mothers whose children were registered in those years,

35 had had up to that time	12 children each.
17 " " " "	13 " "
9 " " " "	14 " "
5 " " " "	15 " "
2 " " " "	16 " "
1 " " " "	18 " "
69	

And among foreign mothers there were counted

making a total of 436 fecund foreign mothers, and only 69 American, the fecundity of the latter appearing, too, in a less degree than that of the former.

Mortality.—I have now reached the most painful portion of my review. In regard to the sanitary condition of Buenos Ayres, I must state facts plainly as I apprehend them to exist, not merely because science should be in possession of the whole truth, but also because the truth may serve a useful end in stimulating the praiseworthy efforts now being made to remedy the evils which menace the public health in that city.

Annual reports of the vital statistics of Buenos Ayres have only been published within the last few years, and always so late as to have lost much of their interest when they have reached the eyes of the few persons who consult them. The public is for the most part ignorant of the number of deaths that have occurred during the year, and is altogether unaware of the proportion existing between the mortality and the population, so that the belief still prevails that the city is very healthy. From time to time such epidemics have appeared as smallpox, scarlatina, or

measles, often carrying away large numbers of people; but such visitations have been regarded as temporary exacerbations of mortality, which, once past, would give place to returning health and all its attendant blessings. In 1858, a yellow-fever epidemic, confined within the narrow limits of a single ward of the city, killed from three to four hundred victims. As the same disease had raged to a fearful extent the previous year at the neighboring city of Montevideo, its appearance in Buenos Ayres produced a profound impression of terror, and caused a large number of the inhabitants to flee to the rural districts; but the epidemic having proved of short duration, and its effects somewhat limited, it was believed that the sanitary condition of the city was so perfect as to prevent the spreading of the horrible malady, and a general complaint arose against the quarantine department for want of vigilance in allowing the introduction of an exotic disease. In spite of the frequent returns of smallpox, scarlatina, and typhoid fever, and the mortality caused by the *tetanus infantum* (popularly called the "seven days' sickness"), and other diseases common among children, the idea of the salubrity of the city still prevailed in the public mind.

In 1867, Asiatic cholera made its first appearance, and the following year it returned, extending its ravages through the surrounding country and most of the provinces of the interior. Much greater, indeed, would have been the alarm in Buenos Ayres, if timely publicity had been given to the disastrous effects of the warnings from Nature, who in no instance allows any violation of her laws to pass with impunity. Much greater, I say, would have been the alarm, for the people would then have been made aware that the number of deaths in 1867 had reached 8029, or 49.9 per 1000 of the entire population, and 38.9 per 1000 in 1868. As it was, however, the evil was productive of some good results: works were undertaken for supplying the city with running water, and the cleaning of the streets, and other sanitary details coming within the province of the municipal police, were more regularly and efficiently performed.

The year 1869 was a peculiarly favorable one for determining the real sanitary condition of the city, there being no epidemic just then in Buenos Ayres, and the general health being, to all appearance, perfectly satisfactory. The census of the population was taken in the year just mentioned, and that was the juncture fixed upon for inquiring into the real nature of the city as a habitable centre, and examining the status of its account current between life and death, always bearing in mind that, after the disappearance of severe epidemics, the relative death-rate decreases in a sensible degree. Now, had a report of the vital statistics then been drawn up and published, it would have exhibited a mortality of 5982 for the year last referred to, or 33 per 1000 of the inhabitants who had just been numbered, and would have shown that, with such a usual rate, Buenos Ayres could not appear to advantage beside other civilized cities, in which latter—even including the most populous of Europe and America—the mean annual death-rate is, with very few and marked exceptions, much lower. Then would the existence have become evident of permanent causes, the removal of which was indispensable in order to the improvement of the public health. It would also have been discovered that those causes tended to heighten the severity of epidemics, and that something more was necessary than merely defending the entrance to the city against the invasion of pestilence (even could such defence, which is rarely the case, be rendered efficacious), namely, the purification of the city itself, in order to render it salubrious under all

circumstances, and to weaken the virulence of disease in the event of extraordinary visitations.

In 1870, peace and prosperity reigned undisturbed in the city, the general health seemed good, immigrants, in hitherto unprecedented numbers, were flocking in, labor was abundant and well remunerated, and capital easily obtained, and commerce and industry were more active than ever before. Buenos Ayres was all contentment, and looked with evident satisfaction upon its visible growth; and the very possibility of another epidemic was forgotten by the people, who supposed the entrance to their city well guarded by vigilant sentinels. Indeed, the death-rate for that year was 1.5 per 1000 lower than that of the year immediately preceding, though still far above the usual rate in other cities between which and Buenos Ayres comparison was allowable. The situation remained unchanged until the early days of 1871, when some cases of yellow fever were reported in the southern extremity of the town. How had the enemy entered, and who was to blame for the neglect? Investigation was idle; the yellow fever, the terrible yellow fever, was in their midst, and the frightened inhabitants anxiously occupied themselves with the thought: what is likely to be the severity, and what the extent, of the visitation? All, families and individuals, who could do so, left the city in search of a refuge from death that stared them in the face. The pestilence, in the mean time, spread apace, and gained in intensity as it spread. It attained its maximum severity in April, and thenceforward gradually subsided until the end of May or beginning of June, when the last cases occurred. The epidemic had extended throughout the entire city. Its ravages were truly awful; 106.5 of every 1000 inhabitants died in that year, including in the population those who were saved by withdrawing to the rural districts—some 60,000 persons. Such mortality was beyond all imagination: one out of every nine inhabitants is a death-rate unprecedented in the civilized world in the nineteenth century; nor is it possible to describe the feelings of anguish and terror which it left in the breasts of the survivors. It then became deplorably evident that the hygienic condition of Buenos Ayres was unfavorable in the extreme, and that the prompt investigation and removal of the causes of the evil, at any sacrifice, were matters of the utmost urgency. Under the promptings and counsel of science and experience, works of sanitary improvement were at once commenced, and on their completion we shall be in possession of that salubrity which is so much to be desired, and which is always the reward of man's efforts to secure it. The lesson has been a severe one.

It is only within the past few years that the beneficial results of Sanitary Sciences have been experienced, even in Europe itself. To know that many diseases are avoidable, inasmuch as their determining causes are known and may be suppressed, is the first step, and comes within the province of science. The will and the means necessary for the removal of those causes are to be applied by the people, through their municipal or political organization. The world has been very tardy in learning to know itself in this respect, and is still slow in reaching the ultimate consequences. It is not, therefore, to be wondered at that Buenos Ayres should have been so ignorant, and still more neglectful than ignorant, of the interests of the public health. Its very rapid growth warrants the presumption that its sociological evolution may possibly partake of a somewhat tumultuous character. Political agitations on the one hand, apt on occasions to assume convulsive forms; inward satisfaction at

66

conscious advancement on the other, with the accumulation of stimuli developed in a feverish and progressive society, and the complete concentration of power, individual and collective, in pursuit of the more material and tangible ends of human energy, have been so many influences tending to divert, and which have in reality diverted, the minds of men from those other interests, more radical and enduring if we will, but less peremptory than the first, because their sphere is not measured by common vision, and because a catastrophe is at times required to bring them to the public attention.

Although the foregoing reflections do not strictly form a part of the principal object of the present review, they bear so close a relation to it that I cannot forbear including them, they having been suggested to me in the course of my statistical inquiries. It also appears to me proper to mention, in this place, the chief causes of the increased mortality, though they differ in no respect from those which—in all cities where the laws of hygiene are imperfectly observed—contribute to augment the number of deaths.

In Buenos Ayres, as in all Spanish towns, the streets are narrow, and they present, together with the few, small, public squares, an area of very inconsiderable extent. It is to be remembered that the proportion of the municipal area to each inhabitant, as mentioned in a preceding page —70 metres—is the average proportion, there being many parts of the city sparsely populated; and it is likewise to be borne in mind that in most houses considerable space is devoted to extensive court-yards, etc. As the population increases, these relative advantages grow less, and they will become altogether null at no far distant day, unless prudent forethought lead to the enlarging of the squares, and the converting them into health-giving parks, and the widening some of the streets into vast and spacious avenues.

In the course of the past twenty-four years, about two-thirds of the city have been rebuilt, but without any attempt having been made to improve that opportunity by adopting a methodical system of widening, save only in the new streets of the suburbs. A grave error was committed in using the filth of the town for the purpose of filling up and levelling some of the streets, which were immediately paved over. The filth thus employed consisted of a heterogeneous mass principally made up of the refuse from the dwellings, that is to say, animal and vegetable matter united with dust and other substances, comprising house and street sweepings. Such a sediment is destined to be decomposed by putrid fermentation, and gives place to the generation of mephitic gases, which escape through the porous surface stratum, and, mingling with the air breathed by the inhabitants, constitute an inexhaustible source of poison for the atmosphere. Indeed, it has been observed that the people dwelling in the wards here described, have been relatively the principal sufferers during epidemics, and that some portions of these districts are rarely exempt from typhoid fever, especially in the spring and summer seasons.

The water formerly used in Buenos Ayres, both for drinking and general household purposes, was derived from three sources; the rich had rain-water, preserved in impermeable tanks or cisterns, and the remainder of the population took well-water and the river-water sold in the streets, which was commonly brought from the portion of the river La Plata contiguous to the town, and was certainly contaminated by the

fluvial population of the port, and by the liquid animal matter flowing down from the slaughter-houses situated on the borders of the Riachuelo, some two miles south of the centre of the city. With the exception of the cistern water, for the most part good, the water chiefly used was necessarily bad, as may be presumed from the nature of the sources from which it was derived. Since 1868, steps have been taken for supplying the town with running water proceeding from a more suitable portion of the river, towards the north of the city; but the supply thus obtained is extremely limited, nor is the source from which it is taken altogether free from objection yet. The extensive works at present in process of execution will accomplish a radical improvement in this respect.

The system of privies was primitive in the extreme. The receptacles of the excrementitious matters were common cesspools, usually sunk below the level of the subterranean water. In the soil, eminently porous in that region, a deposit of putrescible matter was maintained for years, dissolved more and more by the subterranean water, whose level has a mean alternate rise and fall of about six feet from the dry to the wet season. Hence, the process of absorption was rapid; and not only the gases generated by fermentation, but the liquids in which the decomposed organic matter was held in solution impregnated the soil, vitiated the water of the wells, and sent to the surface mephitic emanations incompatible with the good health of the people who breathed an atmosphere thus poisoned. In 1868 a new system of impermeable privies was instituted; but it has not yet become sufficiently general in its application, and since 1871 the plan has been put into practice of emptying and cleaning the privies by a pneumatic mechanism similar to that so successfully applied in France. The works of drainage and sewerage, so actively prosecuted at the present time, are destined to radically remove this infection, which experience has demonstrated to be one of the most fruitful causes of disease and death.

Before closing this tedious enumeration, I must add that there existed two other foci of infection in Buenos Ayres. One of these was an immense heap of refuse, made up of animal and vegetable matter in full course of decomposition, which was accumulated some three miles southwest from the centre of the city, and from which the noxious gases were carried to the town by the atmospheric currents, and mainly by the wind called *el pampero*, blowing in that direction from the pampas, and reputed as the most healthful in the region. The quantity of filth gathered in that place was enormous; in 1873, three hundred tons of the pestiferous mixture were carried off daily, and in 1875, three hundred and ninety tons. Since 1873, the evil effects of the accumulation have been sensibly modified by the simple and most efficient means adopted of burning the unclean matter.

Two miles southward from the centre of the town runs the Riachuelo, which empties into the Rio de la Plata. Here the loading and unloading of the coasting and other light craft are mainly effected; and on the banks of the Riachuelo stood for many years the slaughter-houses and fat-boiling establishments, which represented the two principal industries of the province, and in which as many as half a million of cattle were slaughtered annually, and more than two millions of sheep and mares, and the various parts of their carcasses were prepared for commerce. All the liquid and much of the solid refuse matter proceeding from these establishments were thrown into the Riachuelo. The mass of infection thus

collected may easily be imagined, as may the consequent contamination of the waters by the fermentation of the organic matter, from which arose stifling gases to corrupt the air shortly to be breathed by the inhabitants of the town. So extensive were the interests connected with the ancient and remunerative industry allowed by our legislators to be carried on in the manner described, that, notwithstanding oft-repeated warnings of the grave objections offered by the nuisance, all the terror and desolation of 1871 were necessary to bring about its abrupt suppression. Many proprietors, no doubt, suffered materially by the measure; but the beneficial results to the public health were incalculable. The diminution of the typhoid fever since the removal of the *saladeros*, etc., affords an evident proof of the wisdom of the step.

Is it, then, astonishing that, under so many unfavorable circumstances, mortality should have been so great in Buenos Ayres? If the people had been informed of the number of deaths from year to year, and the relation between that number and the number of inhabitants, they would have seen that, during the years 1854–1872, the death-rate was never less than 31 per 1000, without counting the great epidemics; they would have understood that the severity of the cholera and yellow fever which decimated their ranks was intimately connected with causes within their midst, calculated to encourage the development of contagious maladies; and they would have investigated the nature of those causes, would have found them where all modern societies have found them, and would have energetically set about their removal. They would thus have avoided much grief and many losses of greater moment than the expenditure would have involved. There is no doubt that, if the public health be persistently and intelligently cared for, and past and future experience in this respect be profited by, the rate of mortality will in a few years descend to the level of that of London, the metropolis of the world, as it is called on account of its gigantic proportions. The climate of London is not better than that of Buenos Ayres; nor are the waters of the Lea or the Thames comparable, either for purity or abundance, to the sweet and crystalline streams of the Paraná and Uruguay, which unite to form the Plata; nor is the food used in England more healthy or nutritious than that used in the Platine city; nor is the soil of the former more extensive or more fertile than that which the latter can offer to the present and to future generations. If, in our endeavors to improve our own condition, we use the same enlightened determination which England uses, and which secures for her the respect and admiration of all beholders, we shall accomplish what she has accomplished, namely, the reduction of the death-rate in her large cities from 50 per 1000, near the close of the last century, to 22 per 1000, which has been the mean rate during the last few years.

Let us now see what statistics say in their austere language. Taking a series of fourteen years, from 1861 to 1875, exclusive of 1874, for which I have as yet no returns, but inclusive of 1867 and 1868 with their great cholera epidemic, and 1871 with its yellow fever, the mean annual mortality is found to be 38.9 per 1000. If we leave out the years marked by epidemics, the mean annual rate of the eleven remaining years will be 31.3. But I prefer to present these data in tabular form, for the sake of clearness, and in order that the maximum and minimum mortality in the years referred to may be readily perceived.

Years.	Estimated population.	Mortality.	Rate per 1000.
1861	121,280	3,410	28.1
1862	127,101	4,313	33.8
1863	133,200	4,539	34.0
1864	139,593	4,378	31.3
1865	146,292	5,857[1]	40.0
1866	153,313	5,111	33.3
1867	160,671	8,029	49.9
1868	168,382	6,564	38.9
1869	177,787	5,982	33.6
1870	186,320	5,886	31.5
1871	195,262	20,748	106.2
1872	204,634	5,671	27.7
1873	214,453	5,891	27.4
1875	230,000	6,751	29.3
Mean annual rate			38.9
Mean annual rate, leaving out the years marked by epidemics			31.3

In the foregoing table are included three years of dreadful epidemics. It is beyond doubt that, although the importation of contagious maladies is almost always accidental, the extent to which they spread and the severity of their character are always to be imputed to the sanitary condition of the population, and to the same account is the increased mortality to be charged. The year 1865 likewise figures in the table with a death-rate of 40 per 1000, owing to the fact that the soldiers wounded in the first battles of the Paraguayan war, fought on Argentine territory invaded by the enemy, were brought to Buenos Ayres, and considerably increased the number of deaths registered in the city. Deaths occasioned by war should also appear in vital statistics: they are losses of life; and, sooth to say, the cause to which they are due is among the most easily avoidable. With these observations, the mean annual rate for the period we have chosen may readily be estimated. If we leave out the epidemic years and the first year of the Paraguayan war, the mean annual rate of the ten remaining years will be 31 per 1000.

Let us see the state of things in New York during the same period. As will be observed in the subjoined table, I have adopted the figures of the census returns of 1860 and 1870, and computed the population of the intervening years by applying the mean annual rate of increase corresponding to 1.5 per centum. For the years following 1870, I have, for reasons already hinted in this paper, adopted 2.1 per cent., the mean annual rate of increase admitted by the Board of Health. The State census of 1865 has always been regarded as too low; and such must be the case, for, by comparing the population as set down in that census with the mortality for that year, the death-rate would be 35.4, which is inadmissible, as being out of proportion with the rates of the previous and succeeding years.

[1] Commencement of the Paraguayan war.

Years.	Population.	Deaths.	Rate per 1000.
1861	825,873	24,525	28.4
1862	838,260	23,150	27.6
1863	850,833	26,617	31.2
1864	863,625	25,792	29.9
1865	876,579	25,767	29.3
1866	889,726	26,815	30.1
1867	903,071	23,159	25.6
1868	916,641	24,889	27.1
1869	930,337	25,167	27.0
1870	942.292	27,175	28.8
1871	962,079	26.976	28.0
1872	982,282	32,647	33.2
1873	1,002,909	29,084	28.9
1874	1,023,969	28,727	28.0
1875	1,045,467	30,709	29.3
Mean annual rate of mortality per 1000			28.8

In comparing the two tables, I have only to observe that the death-rate for the years 1872 and 1873, in Buenos Ayres, is lower than that for the same years and the year 1874 in New York, while that for 1875 is precisely the same in both cities; that the number of still-born infants is included in the total of deaths in Buenos Ayres, but not in that of the deaths in New York, according to the usual custom in the United States and England; and finally, that, of the total number of deaths figuring opposite the year 1875 in the Buenos Ayres table, 1041 were caused by smallpox.

Comparative Table of the Rate of Mortality in some American and European Cities in the Year 1873.

Cities.	Rate.	Cities.	Rate.
New York	28.9	London	22.8
Philadelphia	19.6	Liverpool	25.8
Chicago	23.8	Edinburgh	21.9
Boston	28.4	Paris	23.0
Cincinnati	22.8	Bordeaux	26.7
Buffalo	13.7	Berlin	27.8
St. Louis	19.4	Vienna	35.2
New Orleans	37.5	Valparaiso	50.0
Cleveland	19.2	Buenos Ayres	27.4

The statistics of mortality in Buenos Ayres are taken with commendable numerical accuracy; but that alone is not sufficient when those statistics are to form a part of the general vital statistics, for in the tables of these a methodical and scientific classification is required. The classification in Buenos Ayres is defective. The deaths are registered according to the medical certificates, in which is expressed the cause of death; but the diagnosis is not submitted to the criterion of any competent authority; nor are any fixed rules observed in the preparation of the tables. The municipal employés, in their turn, but so long after date as to preclude the possibility of adequate revision and correction, copy down in alphabetical order the diseases mentioned in the physicians' certificates; so that statistics thus compiled leave much to be wished for, in a scientific point of view. The establishment of a uniform system of classification for all countries would be desirable, as much enhancing the advantages to be derived from comparative statistical studies. The classification proposed by Dr. Farr, and approved by the International Statistical Congress in Paris, in 1855, is the one commonly followed in the United States and England; but it has not been adopted in France and

many other nations, nor is it uniformly observed even in the United States. In the reports of the Chicago Board of Health, which I have before me, I find the diseases arranged in alphabetical order, without any regard to their special character.

The publication of the complete statistics of Buenos Ayres would, therefore, be of no practical interest; and so I shall select the latest of a series of reports in my possession—that for 1875—and transcribe therefrom such portions as are necessary. Of the 6751 deaths registered during that year, the prevailing causes were as follows:—

Smallpox	1041
Phthisis	858
Tetanus infantum	445
Typhoid fever	140
Meningitis	355
Pneumonia	382
Organic affections of the circulatory system	389
Diphtheria	101
Diarrhœa	296

The mortality according to sexes was as follows:—

Males	3841
Females	2889
Not specified	21
Total	6751

According to ages:—

Up to 5 years (including 189 still-born)	3521
Up to 100 years	3072
Not specified	158
Total	6751

According to nationalities:—

Argentines	5102
Foreigners	1649
Total	6751

Smallpox stands for 15.4 per cent. of the mortality of the year. Few cities present so large a number; and this is precisely the disease the ravages of which may be most effectually prevented. If vaccination were made obligatory in all cases and by all means, and due care taken to be sure of the efficacy of the virus by frequent renewal, the deaths from smallpox might be reduced to one-tenth of the number figuring in the table; particularly when the hygienic condition of the city should have been improved by the overground and underground sanitary works now in progress. The appearance of smallpox is no longer an accident, but an event of ordinary occurrence; the extent of its ravages is variable, but the disease never fails to come, as proved by the following table:—

In 1869 the number of deaths by smallpox was	183
" 1870 " " " "	195
" 1871 " " " "	1656
" 1872 " " " "	836
" 1873 " " " "	76
" 1874 " " " "	525
" 1875 " " " "	1041
Total	4512

Giving a mean annual rate of 644 during the seven years mentioned. Such figures as these need no comment, nor even comparison with those of American and European cities or regions.

The next item of importance is that of 858 deaths from pulmonary consumption, representing 12.7 per cent. of the total mortality. The death-rate caused by phthisis has sensibly augmented in six years, as will be seen in the following table:—

Years.	Deaths from phthisis.	Rate per cent. of the total mortality.
1869	370	6.1
1870	274	4.6
1871	495	2.4[1]
1872	597	10.5
1873	755	12.8
1875	858	12.7

This progressive increase of tuberculosis, at a time when cases of zymotic disease are tending to diminish in number, save only smallpox, which is due to a specific cause, can only be accounted for by an increase of dampness in the soil underlying the city, in combination with the other causes of insalubrity already mentioned, and which have as yet been but slightly modified. Dr. Buchanan observed the effects of the drainage-works in twenty-five cities in England, and reported that in all of them the general mortality had decreased, particularly that determined by typhoid fever and diarrhœa; but that in those which had been supplied with thorough sewerage, without an equally effective system of underground drainage, neither pulmonary consumption nor catarrhal affections had undergone any diminution. The immediate effect of subterranean drainage is to dry the ground, thus allowing the air to penetrate into the latter and take the place of the water throughout the thickness of dried earth, and there hasten the oxygenation of the infectious substances held in solution, and thereby establish a healthy condition of the soil. Besides, this drying process exercises a powerful influence upon the atmospheric strata immediately contiguous to the ground and forming the air breathed by the inhabitants. It has been observed as an invariable rule, easily explained by physical laws, that fogs disappear or are diminished in a remarkable degree in cities and elsewhere where the ground has been dried by drainage. From the two foregoing facts it may be deduced that the increase of tuberculosis corresponds to the increase of underground humidity in conjunction with other depressing influences; and that if we desire to put a limit to this grave malady, all the more to be feared from its hereditary character, it is necessary that a most perfect system of underground drainage should form a part of the works now in process of execution, not only to prevent the invasion of new masses of water, but to dry up that now contained in the ground, and so remove the existing infection.

Buenos Ayres is not, indeed, the city which offers the greatest mortality from pulmonary consumption. This disease has always been proportionately more destructive in New York. The statistics of fifty-five years demonstrate that, down to 1853, it caused from 16 to 21 per cent. of the total mortality of that city; but that since that time it has diminished in severity, as may be seen by the subjoined table, corresponding to that above given for Buenos Ayres:—

[1] The year of the great yellow-fever epidemic.

Years.	Deaths from phthisis.	Rate per cent. of the total mortality.
1869	3364	13.37
1870	4030	14.82
1871	4186	15.52
1872	4274	13.09
1873	4134	14.21
1874	4034	14.04
1875	4172	13.78

Nor is New York the least favored city in this respect in the United States or Europe, as may be seen from the following table:—

Cities.	Rate per cent. of deaths from phthisis.	Cities.	Rate per cent. of deaths from phthisis.
Boston	15.17	St. Louis	8.78
Philadelphia	14.28	Baltimore	14.55
Portland	25.03	London	11.70
Cincinnati	11.64	Paris	18.90
Cleveland	7.76	Rome	11.00
Chicago	6.68	Naples	15.24

Next in order of numerical importance, on our list of causes of mortality, stands *tetanus infantum* or *trismus nascentium*, the number of victims to which was 445 in the year referred to, or 6.5 per cent. of the total mortality. The peculiar tendency of the soil of Buenos Ayres to determine such a considerable number of cases of *tetanus infantum*, vulgarly called the "seven days' sickness," and in England the "nine days' sickness," is a circumstance deserving experimental and scientific inquiry. This species of tetanus is regarded as traumatic, and as proceeding from the section of the umbilical cord: it may set in during the process of cicatrization. That this is not the only determining cause, is proved by the existence of the disease in the endemic form in the city and province of Buenos Ayres, and, to a certain degree, in the other littoral provinces. That it is dependent upon the impurity of the surrounding atmosphere and the want of care bestowed upon new-born infants, is demonstrated by its almost total disappearance among families comfortably situated in clean and well-ventilated houses; while the chief ravages of the affection occur among the poor, particularly in houses overcrowded with people who either know not how, or are unable, to give their infants that care which is required by their tender years. At all events, the mortality from *tetanus infantum* has been on the decrease for a number of years, owing to the improved condition of the general hygienic police, for I have no doubt of the existence of a zymotic element in the production of the disease.

Years.	Deaths from tetanus infantum.	Rate per cent. of the total mortality.
1869	630	10.5
1870	689	11.7
1871	470	2.2[1]
1872	558	9.8
1873	620	10.5
1875	445	6.5

It is not here possible to establish a comparison with other cities, the tetanus of new-born infants either not being mentioned at all in their statistical reports, or only figuring therein for an extremely small proportion of the total mortality. One exception I should, however, make:

[1] Year of the yellow fever.

the city of Havana, where 388 of the 8390 deaths which occurred in 1875, were caused by *tetanus infantum*, being 4.6 per cent. of the whole mortality.

Typhoid fever was represented in 1875 by 128 deaths. The number of deaths by this disease was 600 in 1869; but it has been gradually decreasing since the suppression of the *saladeros* in 1871, and the destruction of the filth in 1872 and 1873. This, like the other zymotic diseases, is subordinate to the infection of the soil and air, and will prevail in inverse ratio to the progress of the sanitary works now in course of execution.

I shall devote no special remarks to the other causes of death enumerated in the table, partly because they are common diseases, and again because the sanitary improvements will exercise a certain influence upon them. After a brief examination of the subject of mortality among children in Buenos Ayres, I shall proceed to consider the relation in which the various nationalities appear before the law of death.

The number of children under five years of age who died in 1875, was 3521, including still-born infants, or 52.1 per cent. of the total mortality for the twelvemonth. More than one-half of the deaths in Buenos Ayres are of children under the age of five, which proportion is at once extremely large and afflicting, especially as it seems to increase from year to year, as set forth in the annexed table:—

Years.	No. of deaths among children.	Rate per cent. of the total mortality.
1869	2534	42.2
1870	2690	45.7
1871	3591	17.3
1872	2649	45.7
1873	2891	49.0
1875	3521	52.1

Let us compare this table with the following one for New York during the same number of years:—

Years.	No. of deaths among children.	Rate per cent. of the total mortality.
1870	12,971	48.0
1871	13,333	49.0
1872	16,188	49.5
1873	14,182	48.7
1874	13,956	48.9
1875	14,839	48.3

From the comparison it would appear that the relative mortality among children was greater in New York than in Buenos Ayres. But in both cities it is very much greater than in localities the hygienic condition of which is more favorable to general health; while, on the contrary, wherever that general condition is less favorable, infant mortality represents a still higher proportion.

Where a full-grown adult may be able to brave morbific influences with impunity, a tender infant will succumb. The mephitism of cities, resulting at once from accumulation, imperfect circulation of air, defective light, and the gases from decayed organic matter which pervade the atmosphere, menaces the health of all; notwithstanding which, the great majority of adults survives, thanks to fully developed vigor and a confirmed habit of organism, inured, as it were, to these adverse circumstances. But the infant, just emerged from the maternal cloister, ignorant of the circumstances in the midst of which it lives, unaccustomed to the struggle, breathing that impure air from twenty-six to thirty

times each minute, with extremely permeable membranes, and the rapid processes of assimilation required by the progressive development of its organs; the infant, in a word, feeble, inert, and defencelessly exposed to the poisonous air, without knowledge of the evil, and even helpless to avail itself of its locomotory mechanism to enable it to avoid danger under the guidance of instinct, droops, and is prostrated by disease and death. And all this without taking into account the baleful effects of hereditary transmission, by which those tender organisms are unfitted for life, poisoned as they are before birth by virulent infections, which at best doom to a miserable existence the beings who receive them with the blood of their progenitors.

These simple reflections, dictated by common sense, serve to illustrate the incontestable fact that, under whatever hygienic conditions, even the most satisfactory, life is surrounded by most dangers when in its dawn, and that deaths will be more numerons during that period than at any other time with which it may be compared; but the same reflections serve also to illustrate another phenomenon less generally known, namely, that, in proportion to the development of toxic influences in a community, not only will the general mortality be enhanced, but the relative mortality among children will be increased in a still higher degree. This unchanging fact, proved by statistics and never contradicted by experience, points to the conclusion that the proportion of the infant mortality to the total mortality in each community may be taken as a reliable human necrometer, and that from it may be deduced the sanitary condition of that community, even without an absolute knowledge of the population at a given moment.

Supposing, for instance, that New York should succeed in reducing its mortality from 29.3 per 1000, as it was in 1875, to the London rate of 21 per 1000 (which, it seems to me, would be perfectly attainable in a few years, if the remedies pointed out by science were resolutely applied), the aggregate mortality would be 21,954, instead of 30,709, and the infant mortality, which reached 14,839, would not only be reduced, in proportion to the total, to 10,604, but (the rate per cent., instead of 48.3, being only 40, as it is approximately in very healthy cities) would not rise above 8781, thereby saving more than six thousand children annually who are now sacrificed by the fatal circumstances under which they are born to await death. And, if the same reckoning were applied to Buenos Ayres, the mortality in 1875 would have been 4830, instead of 6751, and the corresponding infant mortality would have reached but 1932, and 1589 infant lives would have been spared.

The vital statistics of Buenos Ayres show that, of 6751 who died in that city in 1875, 5102 were Argentines, or 75.5 per cent. of the total number who perished. With the exception of 1871, in which year the number of foreigners who died was greater than that of natives, the latter stand in the death-returns for from 70 to 75 per cent. Indeed, the exception mentioned is to be explained by the fact that 60,000 persons, almost exclusively Argentines, fled and took refuge in the rural districts, while the foreigners (workingmen with their families) remained, for the most part, in the infected town, and bore the brunt of the pestilence. For the sake of clearness, I give the subjoined table, in which are set forth the mortality among Argentines and foreigners, and the death-rate of the former in relation to the total mortality in the city during a period of six years:—

Years.	Argentines.	Foreigners.	Percentage of Argentine deaths.
1869	4203	1,779	70.2
1870	4587	1,299	77.9
1871	8082	12,666	38.9
1872	4121	1,550	72.6
1873	4319	1,572	73.3
1875	5102	1,649	75.5

If we examine the figures corresponding to 1869, which, taken as they are from the census-returns of that year, present the advantage of being accurate, and bear in mind that the native and foreign elements were then almost equal (89,661 Argentines, 88,126 foreigners), we shall observe that the mortality among the former was at the rate of 46.9 per 1000, and that among the latter 20.1. And, if we take into consideration that the proportion of the foreign to the native element has increased from year to year, the marked inequality in the relative proportions of mortality in the two groups will become at once perceptible. The gravity of such an alarming state of affairs as shown by statistics is somewhat attenuated by the fact that, among the number of deaths of Argentines, is included the total mortality of children up to five years of age. Deducting the latter from the death-returns of the same year, 1869, which, as has been seen, is likewise the least unfavorable for the Argentines, and counting as adults (in as far as probabilities of life are concerned) all individuals of upward of five years of age, we shall have:—

Argentines	4203
Children	2534
	1669
Foreigners	1779

that is is to say, a slightly greater mortality among foreign adults. It is, however, to be observed that, of the 23,367 children (up to 5 years) shown by the census, 2290 were born out of the republic. The portion of these among the children who died in that year, and who were naturally registered acording to their respective nationalities, forms a part of the 1779 foreigners of the death-returns, and hence cannot be deducted from the total of the Argentine infant mortality. If 9.8 per cent. of the infant population, up to five years, is made up of foreign children, it is fair to suppose that at least 9 per cent. of the infant mortality belonged to that category, in whicn case the approximate result would be:—

Total of deaths among children	2534
Nine per cent. of foreign children	228
Number of Argentine children	2306

which deducted from the total Argentine mortality, would leave, instead of 1669, a remainder of 1897, a number much higher than that of the deaths among foreigners.

Before proceeding any further with the review of the sad details suggested by the foregoing results, let us compare these with those of the corresponding table for New York, as follows:—

Years.	Mortality.		Percentage of Americans.
	Americans.	Foreigners.	
1868	16,805	8,084	67.5
1870	17,471	9,714	64.2
1871	17,470	9,566	64.7
1872	21,448	11,199	65.6
1873	19,135	9,949	65.7

Taking the year of the census, in which the population was composed of 523,198 Americans and 419,094 foreigners, the mortality among the former was 33.3 per 1000, and among the latter 23.1 per 1000. If the children be also deducted, for the same reason as in the case of Buenos Ayres, the balance of the adult mortality is in favor of the native population, in the proportion of 4671 deaths of adult Americans and 9714 of foreigners, regarding as adults, as usual in my calculations, all the inhabitants of more than five years of age. It is necessary here to make two observations concerning these comparative results. The first has reference to the difference as regards ages, between Buenos Ayres and New York, whence it appears that the inhabitants under five years of age constitute, in the first city, 13.1 per cent. of the total population, as may be seen by the census returns, while in the second they represent but 11.8 per cent., and, consequently, that the mass of inhabitants among whom death makes its most abundant harvest is relatively larger in Buenos Ayres. The second is contained in the following words of Dr. Elisha Harris, recorder of vital statistics of the New York Board of Health: "We next notice that more than half of the total population which is over five years of age is of foreign birth, and that families, the heads of which are of foreign birth, constitute the chief portion of the tenement population, as shown by the returns of census-takers in the different wards." . . . "Vigorous as the better portion of foreign residents are, the rate of mortality in their children is excessive." These statements go to show that the mortality among foreigners of over five years of age, who live under such depressing circumstances, as also among their young children, must be greater than that among the native population, by whom other advantages are enjoyed.

There is in all this something more radical and serious than mere numbers. In order to attenuate the gravity of the vital statistics, the argument of the mortality among children is at all times adduced, and their number deducted from that of the deaths among natives, thereby proving that, from the age of five years upward, the vital energy to resist disease and death is no greater in foreigners than in natives. I do not wish to discuss this point, respecting which much might be said in view of the lessons of history and of the biological sciences; but I must say something upon the subject of the element with which it is asserted that the balance against the native population is closed. Considered in its relation to social mechanics, a child is assuredly not a power, but a resistance; not a force, but a burden; and, according to this incomplete and fallacious theory, the death of a child would only be a loss in the breasts of those who mourned him, and not for the producing capacity of society, especially if replaced by a vigorous adult, come whence he might. Such a doctrine, condemned by our natural feelings, by justice, and by philanthropy, is also in opposition to the dictates of sound reason and statistics. Socially, the child is the moral bond and the hope of the family; politically, he is the citizen of the future. The citizen who has been born and grows up in the land of his fathers, not only assimilates the materials of his organism in the continued process of rapid renovation, but takes in, in that atmosphere, the constituent elements of his disposition, and thus becomes by progressive education, by the contemplation of vicissitudes and of the struggles of manhood, and by the innate love of all belonging to him, the surest guaranty of the firmness of the institutions under whose influence and in whose mould he has been formed. It is, then, the duty of well-constituted societies to bestow

attention upon their children in view of the double interest just referred to, and, if for nothing else, for the purpose of preserving the largest number possible for the battles of collective life.

If the mortality among Argentines in Buenos Ayres, and among Americans in New York, should become enhanced, or even retain its present proportions, it would be difficult to foretell how far the respective nationalities may become weakened as a ruling power in society, and how, little by little, that loss of influence may be felt in the customs of the people and the integrity of the institutions. In my opinion this danger is neither imaginary nor remote, and the only means I can discover by which it may be averted (and I have long studied the subject) is, by the energetic improvement of the sanitary conditions of states, cities, and towns; the reduction of mortality to its lowest possible expression (18 per 1000, for instance); and the perfecting of the systems of education, popular, moral, and physical. From what we have already seen concerning the susceptibility of favorable or adverse influences in infancy, if mortality be lessened, those most benefited thereby will be the children; while society, by the preservation of a larger number of these, will secure the organic advantages which I have mentioned.

Statistics have also a voice in the question. The city of New York, during the seven years ending in 1873, had a mean annual death-rate of 29 per 1000, while the rate of births for that period was very low. Taking the figures as they stand in the register, the number of deaths and births was as follows:—

Deaths during the seven years	189,385
Births " " " "	119,226
Difference against the population	70,159

which is equivalent to a loss of more than 10,000 per annum. So that if such losses were not compensated, and even exceeded, by immigration, the population would go on gradually decreasing. I should here mention that, according to official reports, the registry of births is so defective as to warrant the assumption that not more than 75 per cent. of the real number is recorded. Even accepting this hypothetical suggestion, and supposing no omissions to have occurred in the death-registers, we should have:—

Deaths	189,385
Births	158,968
	30,417

which would still leave a considerable loss for the population. And, in order to avail ourselves of these figures, let us suppose the mortality in New York to be reduced to 21 per 1000; in which case we should have the following results:—

Deaths	140,692
Births	158,968
	18,276

leaving a balance of 18,276 in favor of the population, in place of a real loss, as it has been sustaining; and this without taking into account the positive fact, based on experience, that the number of births increases with the improvement of the sanitary condition of the city. It is likewise to be borne in mind, respecting children, that mortality among them decreases much more rapidly with an improved healthy condition

of the city than among adults; so that, if, of the hypothetical number of deaths (140,692), 40 per cent. had been of children, the mortality of the latter would have been 56,276, instead of the 93,677 who died during the seven years, thereby constituting an economy of 37,401 infant lives, or as many fathers or mothers of families in the course of a few years.

During the same seven years, Buenos Ayres had 51,207 births and 58,771 deaths, including the three epidemics (1867, 1868, and 1871), or a loss of 7564 inhabitants. By reducing the annual death-rate to 21 per 1000, the mortality would have been 27,455 in the seven years, and the difference in favor of the population 23,752. I am not examining chimeras, but realities; death and life are recorded in official statistics, and the improvements which I hold as possible are graven in imperishable monuments, in the form of sanitary works, in those American and European communities which have struggled gloriously with death, and have conquered it.

Wherever there is death there is sickness. It is generally admitted, and to a certain extent proved by statistics, that the sickness-rate of a city or town is approximately two sick persons throughout the year to each death per annum. Hence, to ascertain the number of days of sickness suffered by the population, taken collectively, the permanent factor 730 (365 × 2) is multiplied by the number of deaths during the year: so that when the mortality is considerable, the number of sick persons is also considerable in like proportion—which is perfectly reasonable, inasmuch as sickness and death proceed from the same causes acting, in a given locality, upon each and all of the inhabitants. In 1875 the mortality of New York was 30,709; and, if, as has been admitted, there were two sick persons for each death constantly throughout every day in the year, the number above given should be multiplied by 730, and the product, 22,417,590, would be the number of days of sickness suffered by the population collectively, which is equal to 21.4 days for each inhabitant.

One day of sickness signifies one day's labor lost for those at an age for working and producing. The number of these is easily computed when we know that, according to the census of 1870, there were in the city 350,556 persons engaged in all occupations, that is to say, 37.1 per cent. of the total population; and, by applying this percentage to the population in 1875, we ascertain that as many as 387,769 persons were working, each one of whom lost by sickness 21.4 days of work in the course of the year, and all of them collectively 8,298,566 days. The remuneration for work varying considerably, according to the nature of the occupation and individual capacity, it is not easy to adopt a uniform standard; so I shall take the lowest rate said, by the Commissioners of Emigration, to have prevailed in 1875 for persons working by the day, namely, $1 to $1.50, preferring the first, in order to avoid all appearance of exaggeration. The value of the labor lost would amount, at the rate of $1 per day, to $8,298,566. The expenses occasioned by sickness are incident to the whole population; and the number of days' sickness, for population collectively, as above reckoned, was 22,417,590. The approximate amount of such expenses may be ascertained by means of the data furnished by the hospitals, and according to which each patient costs about $2 per day. Now, reducing those expenses by one-half (say to $1 instead of $2), and including therein the outlay for professional attendance, medicines, regimen, and nursing, for the inhabitants of all classes, the aggregate cost would be $22,417,590, corresponding to the number of days of sickness.

I shall not present in the pecuniary form the depressing influence which morbific causes exercise upon the capacity, physical and moral, of those individuals who, by reason of their vital energy, can resist the effects of such causes and preserve their health. To eliminate and prevail over a pathological agent, implies a waste of organic force in the process, and so much less force in the physical and moral aptness applied to production. *Mens sana in corpore sano.* It is enough to mention this last branch of the subject, the pecuniary value of which cannot be estimated.

Those who die during the working age have an independent value as capital irrecoverably lost. Not only the days of sickness, or the days of the year, are here lost, but the very instrument of production itself for the future. In the United States, an adult immigrant is estimated as representing a capital of $1000 incorporated in the national wealth: now 8580 adults, approximately, died in 1875, in the city of New York, figuring consequently for an aggregate of $8,580,000.

With these numbers, every figure of which I have carefully calculated according to data, either official or of acknowledged scientific authority, the losses in the account of the public health for 1875 may be posted in the ledger of the city of New York, as follows:—

Work lost	$8,298.566
Loss, expenses incurred by sickness . . .	22,417,590
Loss, adult lives	8,580,000
	$39,296,156

These losses cannot be avoided, but they may be considerably diminished. If the mortality had been 21 per 1000, instead of 29 per 1000, each of the items of the account would have been reduced in the same proportion; the aggregate would only have been $28,452,216, and there would have been an economy of $10,838,840.

That amount of money saved would be equal to the interest of a capital of $150,000,000 at seven per cent. And let it be asked of the distinguished Dr. Chandler, President of the Board of Health, or of the most skilled and experienced Sanitary Engineers, either of this country or of Europe, if that capital, or one-half thereof, intelligently invested in sanitary improvements in the city of New York, would not be sufficient to place that city on the level of London in point of salubrity. I am as certain that the reply would be in the affirmative as I am that never could money be invested in a more remunerative speculation.

As for the causes of the evil, and its remedy, there is a set of books which contains their explanation, and which is worth a whole library. The Reports of the New York Board of Health enumerate those causes, accompanied by eloquent suggestions of remedies, from year to year, supported by the authority of science and study. If the reading of those Reports were rendered popular, the influences which make an imperial metropolis an unhealthy city, in the eyes of the laws of hygiene, would be recognized; people would then know in what mortiferous conditions live one-half of the population, and how those conditions may be materially improved, and what are the existing defects in the system of drainage and sewerage, and the danger of those defects being enhanced, to the still greater detriment of the public health; the relations of meteorological phenomena to the mortality of the city would be discovered; and for each and every one of those evil influences would be found a certain remedy, suggested by experience both at home and abroad, or

the means of attenuating such influences as were not immediately dependent upon the hand of man. The recommendations of the board of health, once put into action, with the amplifications required by successive developments, would be sufficient to reduce, within the space of five years, the mortality of New York from 29 per 1000 to 21 per 1000, and thus secure all the benefits, physical and moral, to be gained by such a triumph.

It is for the interest of all, both poor and rich, natives and foreigners, to aid in the realization of sanitary improvements, which are peremptorily urgent for the present and necessary for coming generations. And it must be remembered that the cost of their execution is enhanced by every day's delay. One of those omnipotent movements of opinion which in a strong-minded people are commonly attended by prodigious results, would lead to the immediate and complete solution of the grand problem. Nor does this subject concern alone Buenos Ayres, in that far-distant region of America, nor New York, in this part of the continent: it is a subject which affects the interests of whole nationalities. New York, in 1790, had 33,000 inhabitants; eighty years later, with a million of souls, it is the third city of the Christian world, and is marching onward to become the first, at the close of the second centennial of the United States. Philadelphia competes with Berlin and Vienna; on the banks of the Mississippi is rising up St. Louis, another city which would monopolize the admiration of all who beheld it, were it not that on the margin of Lake Michigan, Chicago rears her head in pride before the astonished gaze of natives and foreigners—Chicago, the new born city, which now contains half a million of human beings. What, in the course of time, will become of these grand centres of civilization, and of many others as yet without a name? The problem of their destiny is in their own hands, and Sanitary Science should be the chief light to guide them.

The tendency to centralization, with its advantages and inconveniences, is inherent in human nature, and not to be controlled. In 1860, there were in the United States 18 per cent. of the total population in cities of 8000 inhabitants and upwards; and in 1875 the aggregate population of the cities of 8000 and upwards amounted to 10,116,000, or 24 per cent. of the total population, this last being estimated at 42,000,000. And this in spite of the agricultural interests which should tend to disseminate the population over the entire length and breadth of the land; spite of the rivers and lakes, canals and railways, the aggregate length of which would reach three times round the terrestrial globe; spite of all these facilities for cheap and rapid transit for people and industrial products, whithersoever called by the necessity of the market.

In the Argentine Republic, this instinctive force of centralization is still more marked than in the United States, and that for reasons, economical and geographical, which are readily perceived. The growth of the littoral towns is proportionately much more rapid than that of the towns in the interior, and particularly that of Buenos Ayres, where the agglomeration is altogether incommensurate with that observed elsewhere in the country. This is not a suitable time to inquire into the sociological and political consequences of this natural inequality; but, in treating of the life of cities and of the statistics of Buenos Ayres, to the latter are applicable such considerations as that species of agroupment may suggest. As for the causes of the excessive mortality of Buenos Ayres, they have now been briefly enumerated, as have also the measures undertaken for their removal.

For the rest, in the sanitary condition of cities, whatever be their population, it is incumbent, not only upon them, in as far as their circumscribed capacity may extend, to assume the responsibility of the present evil and of its future aggravation, but upon each and all of the inhabitants: all have to take part in the continued struggle in defence of life, as well individually as in municipalities, legislatures, and congresses. I know not whether the illustrious Cobden and Peel concerned themselves little or much with matters of public hygiene, but I do know that the liberal commercial legislation established by them in England, has served to improve the condition of the poor of that nation, by rendering their existence less burdensome through the lower prices of articles of food, and has contributed effectually to lessen the number of deaths and of those diseases which are induced by want.

In closing this paper, I feel it my duty to apologize for the liberty which I have taken of instituting comparisons with the vital movement of New York, without the authority of prolonged personal observation. On one hand, I should say that the Argentines ever look to this part of the world for example and stimulus; and on the other, that I have noticed such close anthropological analogies between what I have seen during my short stay in New York and that which has long been the object of my study in Buenos Ayres, that I have not been able to resist the desire of establishing a few comparisons, even at the risk of arriving at defective or inaccurate conclusions.

THE GENERAL SUBJECT OF QUARANTINE, WITH PARTICULAR REFERENCE TO CHOLERA AND YELLOW FEVER.

BY

JOHN M. WOODWORTH, A.M., M.D.,

SUPERVISING SURGEON-GENERAL, UNITED STATES MERCANTILE MARINE-HOSPITAL SERVICE.

The earliest recorded measures instituted to prevent the spread of disease were adopted by Moses, who made regulations concerning the leprosy, in which he not only provided for the isolation of the infected people, but held the suspected for observation and cleansing. In the fourteenth century, certain restrictions were placed upon vessels arriving at Venice and Genoa, in Italy, to prevent the introduction of the plague, but it was not until the fifteenth century that quarantine was generally established.

The early system of quarantine was not based upon scientific facts or experience, but appears to have been an outgrowth of that peculiar period (noted for ignorance and superstition) known as the "dark ages." The name "quarantine" fairly indicates the hypothetical extravagance which held sway at its birth. As out of the *forty days'* fast in the wilderness grew *Lent*, the period of abstinence instituted for the purification of the soul, so the process of purifying ships and passengers from so called contagion was made to cover forty days, and this process was termed quarantine.[1] In the measures blindly enforced to protect seaports from infection, not only was commerce crippled, and property needlessly sacrificed, but the comforts and rights of the suspected were entirely ignored. They were not only compelled to undergo a tedious, and worse than useless, period of observation, but, by the very process of sequestration, they were exposed to tenfold greater danger from fomites that might chance to be in the ship. Many of the senseless and inhuman practices which grew up under the name of quarantine, have by degrees, and from time to time, been discontinued, and yet—so hard is it to cut loose from the influence of tradition—not a little of the fog and delusion associated with the term "quarantine" in the past continues to the present day, especially in the countries where quarantine was first established.

As the visits of the plague became less frequent and less severe, yellow fever and cholera commenced their migrations. These diseases gave a new interest to quarantine, which had previously been confined in its operations to the old world, but by these diseases was extended to the new. To the quarantine of ships, and of those who travelled by them, was added the "*cordon sanitaire*" against cholera, in the hope of preventing its march by land. This last measure has been enforced in Europe with the utmost rigor, and, though utterly futile in its results, appears

[1] Charles Caldwell, M.D., on Quarantine, 1837.

not to have been entirely abandoned in some localities even during the prevalence of the last recorded epidemic of this destroyer.[1]

In America, quarantine was first established in 1758, at New York, against yellow fever. Though I shall have occasion, further on, to speak of the administration of quarantine at New York, it serves to mark the progress and application of experience in this direction to note here some of the changes which have taken place at that port. In 1811, we find that vessels arriving from infected districts were detained thirty days at quarantine, and passengers and crews twenty days after the occurrence of the last case of yellow fever. In 1830, healthy persons arriving in vessels from infected localities were permitted to proceed to the city, but without their baggage. Notwithstanding that many pernicious restrictions still stand upon the statute-books of the State, the enforcement of them is left to the medical officer, whose opinion is more and more recognized. It is now found practicable not to detain either healthy passengers or infected vessels. This arises from the generally accepted principle, that healthy individuals do not convey the morbific poison of cholera or of yellow fever, but that the poison finds lodgment in confined clothing, and especially in the vessels themselves, under favoring conditions. To detain an infected vessel has been found to increase the virulence of the poison. Accordingly, the ship's cargo is promptly transferred to lighters in the bay, freely exposed to light and air, and the vessel, after thorough disinfection, is allowed to proceed. In strong contrast with the foregoing, is the practice pursued at Pensacola, on the Gulf Coast. In May, 1874, upon the arrival of yellow fever at quarantine, the City Council of Pensacola passed an ordinance which is here given in full:—

"Saturday, May 30, 1874.—Board met, pursuant to call from Mayor. The object of the call having been stated, on motion it was resolved that all vessels arriving at this port from infected ports shall be compelled to remain in quarantine until frost; or said vessel shall be allowed to depart from this port at any time during quarantine, at the option of the commander or captain of said vessel; but in no case shall any such vessel be permitted to load, take in, or discharge, cargo, within the limits of the quarantine station during the existence of quarantine; nor shall any person being on board any such vessel be allowed to visit the city during quarantine.

"Resolved further, that the Mayor be requested, and he is hereby fully authorized and empowered, to employ a good and sufficient armed guard, with a good and sufficient boat, to patrol during the night on an established line between the quarantine station and this city; and that the Mayor be requested to instruct said guard to prevent all communication whatever, by boat or otherwise, between said station and this city, and to use sufficient force to attain that end, should it be necessary to fire into the person or persons attempting to violate said quarantine.

"Attest: M. P. de Rioboo, *Clerk*."

The results of these widely different methods may be stated in a few words: During each of the past five years, and more, a number of infected vessels arrived at the New York quarantine station. Many cases of yellow fever were treated in Quarantine Hospital, but in no instance did the disease spread to the city, or affect a single attendant on the sick. At Pensacola, in 1874, the infected ships were anchored near the quarantine

[1] Dr. Milroy, in an article in the British and Foreign Medico-Chirurgical Review, No. lxxxiii., states that "in 1867 military cordons were drawn around the infected districts in Montenegro, and persons who dared to cross them were shot. The horrors of famine were thus added to those of pestilence."

station. Communication from the infected vessels and from quarantine was had by night with the land; and when, under the fostering conditions for propagation, the yellow-fever poison had gained sufficient virulence, the disease spread to the city and the naval station near by, the quarantine medical officer himself falling a victim to the system which he had blindly endeavored to carry out.

In passing to a brief notice of quarantine regulations at two other ports of the United States, it is proper to mention the fact that the control of quarantine in this country is not assumed by the general government, but that it is established and enforced by each seaboard State, or municipality, for itself. The only exception occurred during the war of the rebellion, when the commanding general of the Union armies, upon the recommendation of the Surgeon General of the Army, directed (1) that all vessels arriving from ports infected with cholera, but having had no case during their passage, should be quarantined for fifteen days and thoroughly fumigated, and (2) that all vessels having had cholera on board during their passage, should be quarantined for fifteen days after the termination of the last case, and thoroughly fumigated.

The quarantine regulations at the port of New Orleans, in 1822, authorized the health officer, in his discretion, to continue quarantine indefinitely, but provided that infected vessels should be detained not less than fifteen days after the recovery of the sick, and purification of the vessel. Healthy vessels from healthy ports were detained five days, and "vessels from any port of Europe, arriving between the first of May and the first of November, bringing more than twenty passengers, were not, however healthy, permitted to come within three leagues of the city, until after the first of November in any year."[1] A committee on quarantine for the State House of Representatives of Louisiana, reported that "during the last year [1822], notwithstanding the *strictest compliance* with these laws, our expectations were frustrated at the very moment when we thought we could indulge the hope of the most complete success." Under the present laws in force at the New Orleans quarantine, vessels hailing from ports infected with yellow fever are allowed to pass to the city after ten days from the date of leaving an infected locality, and in this period is included the time consumed in the passage. The Spanish bark Valparaiso, which introduced yellow fever into the United States in 1873, arrived at the quarantine station below the city of New Orleans on the 24th of June, eight days out from Havana. She completed the two remaining days of quarantine required by law, and having been twice fumigated with chlorine, and carbolic acid having been used in her pumps, she proceeded to the city, where the mate was attacked on board on the fourth of July, and died. Eight days subsequently, the mate of a steamboat, laid up for repairs at the same wharf, was also attacked, and died. The first case of the cholera epidemic of 1873, in the United States, occurred at New Orleans in the month of February, when quarantine is not enforced. The man who first died of the disease had resided two months in New Orleans, and at the time of the attack was engaged in discharging cargo from a Liverpool vessel.

Under revised quarantine laws adopted in South Carolina in 1869, healthy vessels arriving at the port of Charleston, in that State, from infected ports, are detained from fifteen to twenty days, and thoroughly

[1] History of Quarantine in Louisiana, from 1821 to 1846. By B. Dowler, M.D., New York Journal of Medicine, 1846, p. 160.

cleansed. If no case of disease be developed, the vessel is allowed to proceed to the city. If, however, cases of disease have occurred on the passage, the vessel is subjected to a quarantine of thirty[1] days, or longer; all sick are promptly removed to the lazaretto, and the vessel is disinfected as before. Under the careful enforcement of these rules, no case of yellow fever has entered the city, notwithstanding that the disease has been brought to quarantine every summer, except in 1871. In the latter year, when no recognized case arrived by ships, the disease broke out in the city.

Turning from the diversity of opinion, practice, and results of quarantine, in this country, we observe a most rigid quarantine enforced by countries bordering on the Mediterranean, while England has, during late years, maintained the free *pratique* of her ports. Because England, from her climatic conditions, comparative isolation, and wise measures of internal sanitation, is able to maintain this advanced position, it does not follow that the seaports of the continent can with impunity conform to her example. In India, the endemic home of cholera, quarantine has proved unavailing, and thence, from the standpoint of some observers in that country, it is argued that measures to contravene the progress of cholera are useless. Were quarantine to be established in the West Indies against yellow fever, it would require no prophetic foresight to predict the result. The conventions of Paris, Constantinople, and Vienna have happily done much to harmonize the conflict of opinion which has prevailed in reference to the particular system which should be applied in quarantine. This system, however, must necessarily be modified by the geographical position and climate of the countries concerned.

To ascertain, as nearly as possible, what precautions are necessary, and what restrictions superfluous, in the administration of quarantine, the next step will be to consider the characteristics of cholera and of yellow-fever propagation, in order to determine as nearly as may be the prophylactic value of *Port Sanitation*, a term which most definitely expresses the practical measures indicated by experience.

Cholera.—Amongst the many views respecting cholera, it is generally admitted that the endemic home of the disease is India, especially the valley and delta of the Ganges, and that it is caused by a specific poison capable of reproduction or multiplication. Whether the endemic existence of cholera in India is due to peculiarities of air, temperature, soil, or water, or to the filth of uncleanly masses of people, is not determined; but it is undoubtedly true that each and all of these influence the propagation of the poison, and the spread of the disease outside of India. Some of the apparently well-established facts respecting cholera in India are: (1) That it only prevails epidemically at intervals, usually of several years; (2) that since its first migration around the world, it has not passed the border of its endemic home to prevail epidemically in other countries, except at times when the disease has shown unusual virulence and diffusion in India; (3) that the number of persons attacked in the same town or city, during different epidemics, varies considerably, even where the surrounding conditions are apparently equally favorable to the spread of the disease; (4) that it is possible to flee from it,[2] showing that a locality or place is the centre or focus of infection; (5) that

[1] Dr. Lebby, the Health Officer at Charleston, has recently informed me that, at the last session of the legislature of South Carolina, the period of quarantine was reduced to fifteen days.

[2] The mountains of Lebanon have always proved a safe retreat for the inhabitants of the cholera-stricken cities of Syria.

recent improvements in the sanitary condition of jails in India have rendered them almost exempt from visitation by cholera, many escaping entirely, and very few of those attacked suffering with severity;[1] and (6) that attendants upon the sick, in cholera hospitals removed from infected localities, do not suffer more than any other class, and usually enjoy entire immunity.

Dr. Cunningham maintains that the spread of cholera does not depend in any degree upon the use of drinking water polluted by cholera evacuations. Over against this statement is to be placed the fact that the mortality rate from cholera has greatly diminished in Calcutta,[2] since the introduction into that city of water less liable to contamination than formerly.[3] The fact that those attacked by cholera, and those who escape, in any given locality, drink from the same wells or other source of water supply, is not proof positive that the cholera poison may not be conveyed through the medium of drinking water, while the condition of individual susceptibility remains as an undisputed factor in the development of the disease. Many undoubtedly receive the poison who do not suffer from it. Proof does not exist of cholera arising from impure water, uncontaminated with cholera dejections, but the cholera poison is unquestionably intensified in its action, or the susceptibility of individuals increased, or both, by the use of drinking water containing organic impurities. Experience outside of India[4] abundantly proves that the cholera-principle is portable; that it is carried by ships, and in clothing and baggage, when excluded from the light and air. The spread of epidemic cholera is characterized by localization in particular places, ships, or houses, which then become centres of infection. The activity of these *foci* of infection, as well as the intensity or fatality of the disease, appear to depend upon certain causes associated with the aggregation of human beings, and the attendant evils of impure air, impure water, and filth. When these are present, a mild case of cholera serves to kindle an epidemic as readily as a spark from the hunter's flint may kindle a fire in the dry, rank grass of a Western prairie; and the progress, controlling influences, and results, of both sparks, are not dissimilar. Individuals, infected with the disease, who travel during the period of incubation, may, under favoring conditions, set up new *foci* of infection at the places where they are attacked. These "favoring conditions" are both individual and local, and, when either are absent, the cholera germ may slumber, or may lose its reproductive power altogether. The non-receptivity of certain localities, and of individuals, has long been recognized, and is undoubtedly due to good sanitary conditions.

There is strong reason for believing that cholera dejections, which appear to be harmless in their fresh state, become actively poisonous

[1] Report of the Cholera Epidemic of 1872, in Northern India; by J. M. Cunningham, M.D., Sanitary Commissioner with the Government in India.

[2] British and Foreign Medico-Chirurgical Review, July, 1872, p. 56.

[3] Prof. von Pettenkofer states that whole towns in Germany, which were ravaged by cholera during former visitations, have been entirely free from the disease during late epidemics, and that this result has been brought about by thorough and efficient drainage, and by purification of the water supply.

[4] Both Dr. Cunningham and Dr. Bryson maintain that cholera is not spread by traffic or human intercourse. The difficulties in the way of proving or disproving the portability of the cholera-principle in a country where the disease originates, are too apparent to give any weight to this negation. The causes or vehicles which spread a disease, not contagious in the sense in which smallpox and typhus are contagious, can only be determined, if determined at all, outside of the endemic home of the disease.

with the commencement of fermentation or decomposition. Acid disinfectants interrupt or prevent altogether the fermenting process, thereby destroying the poison. In like manner, the acid secretions of a healthy stomach are believed to neutralize or render innoxious a certain amount of the cholera-principle. The almost universal testimony is that good sanitary conditions lessen the influence of the attack, restrain its dissemination, and frequently ward off the disease entirely. Dr. Harris has remarked, in referring to cholera in New York, in 1866, "interpret it as we may, the events in the experience of that visitation of cholera demonstrated the practicability of dealing with the transportable and exotic, or germinal, factor of the pestilence as an enemy to be held in restraint, and its propagating attribute to be destroyed—a pestilence to be *stamped out* by definite hygienic measures."[1] There is abundant proof that the specific poison of the first cholera epidemic in the United States, and of succeeding epidemics, down to the last one, was introduced by ships from Europe, and the testimony of European observers furnishes conclusive evidence that the disease was imported into that country from India. The last epidemic of cholera in this country has differed from previous epidemics, in that direct connection between the initial cases and an imported germ has not been established,[2] but the fact remains that nearly two thousand emigrants from cholera-infected districts of Europe arrived in New Orleans during the month of the outbreak and that immediately preceding.[3] It may be stated, as a general fact, that each period of epidemic prevalence of cholera in America has been associated with a similar period in Europe.

The morbific principle of cholera has from time to time shown a disposition to permanent lodgment by surviving the winter seasons of Europe[4] and America. In the epidemic of 1854, in this country, the disease spread to the Pacific coast, and was several times re-imported from Central America to the port of New York; but the generative principle of each epidemic has finally died out, and each succeeding epidemic has depended upon fresh importations from India.[5] Emigrants from infected districts have always been a prolific cause of intensifying and spreading the disease. "It is a matter of common experience to find that at times, when the disease is only of occasional or sporadic occurrence in Calcutta, emigrant ships leaving the port are scenes of severe outbreaks."[6] The readiness with which a vessel takes on the characteristics of a crowded community or city, and becomes a centre of infection, will be more readily appreciated, and the measures to prevent the spread of cholera by ships more wisely directed and applied, when it is considered that a ship is but a town afloat. The ill-ventilated hold and

[4] Drs. Pelikan and Arkhangelsky have shown that cholera was present in Eastern Europe from 1847 to 1856, and again from 1865 to 1873, though evincing a feeble activity during much of the time.

[5] Prof. von Pettenkofer maintains that "it is a fact independent of all theory, which has been observed in every epidemic of cholera, in every place, and on every occasion, that the attacks in each individual house terminate on the average within twelve or fourteen days." Cholera, How to Prevent and Resist it. By Dr. Max von Pettenkofer. Translated by Dr. Hime, 1875.

[6] Calcutta Review, 1869.

foul bilges are the counterpart of the filthy sewers and cesspools of a filthy city.

Yellow Fever.—Yellow fever is a disease produced by an invisible poison, capable of self-multiplication outside of the human organism. This something—the germ or miasm which has hitherto eluded microscopical demonstration—is a product of the tropics. It shows a disposition not to spread in high, salubrious lands, but exhibits a preference for low regions, especially the filthy portions of cities. Filth and high temperature are as truly its concomitants as cleanliness and cold are opposed to its lodgment or propagation. In this country, yellow fever has prevailed in most of the Atlantic and Gulf cities, and in many of the towns along the Mississippi River.[1] In some instances it has been carried inland with people fleeing from infected localities, but it has never shown a disposition to spread epidemically at points remote from the continuous water-roads of commerce. The cities of the great lakes have always been exempt from the disease.

In considering the morbific cause of the disease, we are necessarily restricted to an examination of its characteristics or comportment, exhibited in different places and under different conditions. We are, however, met at the outset with the difficulty and uncertainty of distinguishing between yellow fever and the pernicious malarial fevers of the Gulf coast. The cases that end fatally furnish reasonable certainty of the diagnosis given, but the milder cases that recover scarcely escape from doubt.

This uncertainty in determining the nature of mild cases, divides the profession on the question of the endemic lodgment of the disease on the Gulf coast, and serves to complicate the question of quarantine. Whether the disease was endemic in the intertropical islands of America, before it was brought from Africa, is uncertain; but there is no doubt now of its permanent lodgment in the West India Islands. The fact that the island of Key West, off the southern extremity of Florida, is in daily communication with Havana, makes it extremely difficult to determine the question of importation at that particular point. The weight of evidence, however, is against the assumption of an indigenous origin of the disease in the border lands of the Gulf, but it is probably true that the poison has there been preserved through the winter in fomites, though it is believed that the United States is not affected epidemically except by the imported germ. The germ is transmissible. It is capable of being transported in the personal effects of passengers and sailors, but the damp, filthy holds and bilge water of ships are its favorite lurking places, where, if confined, it multiplies and increases in virulence to such an extent as not only to affect those on board, but even to exert its pernicious influence in the direction of the currents of air to a considerable distance. A vessel anchored at a wharf in Havana, or other infected place, appears to become, for the time being, a part of the infected region; and in sailing to a distant port, the ship transports the poison as surely as could be done by transplanting a section of the infected island of Cuba itself, were this possible.

Yellow fever is not communicated from the sick to the well, the sick being dangerous only as possible carriers of the poison-germ or miasm; hence all persons from an infected district may safely be considered as

[1] Greensville Dowell, M.D., of Galveston, states in his forthcoming work on the History of Yellow Fever Epidemics, etc., in the State of Texas, that "yellow fever has spread to 228 cities and towns, and in 28 States in the United States, appearing 741 times, and causing 65,311 deaths."

harmless when the period of incubation, which lasts from two to six days, has passed. This simplifies the question of quarantine, and indicates the direction of preventive measures to the vessel and cargo, or to the locality, if the poison have found lodgment on shore.

We have come now to the question of practice, and to the consideration of the methods which should be pursued to secure the greatest protection to the public health against cholera and yellow fever, with the least restriction upon commerce. We may differ on the questions of the nature and modes of propagation of cholera and yellow fever, but it is believed that all meet on the common ground of prophylactic measures, and will accept the proposition of *General Sanitation*—applied to the endemic abodes of cholera and yellow fever, to ships, and to exposed countries—as the surest means of stamping out these diseases. The general question of preventive measures, is one intimately associated with that of higher civilization. Every improvement in India, in matters of drainage, in securing pure drinking water, and in personal cleanliness of the people, will tend to lessen the ravages of cholera there, and to diminish the chances of its spread abroad. In the West Indies, the harbor of Havana is most frequented by commercial people, and is the most prolific source of yellow fever.

In a recent personal letter to myself, Dr. Peters has expressed the opinion in reference to Havana, which he had just visited, that "an international public sentiment should be created against the filthy and careless ways of the authorities, which cause so much suffering and death among the mercantile and public navies of the whole world. The harbor is small and landlocked; all the drainage and sewage of the city go into it, and very little gets out of it." Dr. Peters suggests that a canal could be made at the head of the harbor, to the ocean, allowing the tide-water to sweep through the whole harbor, and thus remove its unhealthfulness. A vessel exposed to the influences of an infected harbor may not be able to escape, but the danger can be greatly lessened by enforcing strict cleanliness of the men and vessel. The bilge should be changed every day with sea-water, until the pumps bring clear water. The men should be compelled to bathe and change their flannels daily, when their work is done, and should not be allowed to sleep on the open deck, or in the lower part of the vessel. The same precautions should be continued through the voyage from a yellow-fever port. Ventilation should be freely encouraged, and no confined air allowed in any part of the vessel, if it be possible to prevent it. There is an example of a ship trading between New York and Havana, on which these precautions have been strictly enforced for a period of twelve years, and not a single case of yellow fever has occurred on board.[1] The proprietors of a line of steam-vessels, trading and carrying passengers between West India ports and New Orleans, employed an experienced person on each vessel, during last year, to supervise its sanitary condition and to disinfect it after the discharge of each cargo, with a similar result.[2]

I have already described the manner in which a ship becomes infected with cholera, and, as cleanliness is the great end to be attained, and maintained, on shipboard, the general preventive measures against this disease are not unlike those suggested against yellow fever. If, however, one or more persons are seized with cholera on board a vessel, they

[1] Communicated by Dr. Vanderpoel. [2] Communicated by Dr. C. B. White.

should be separated from the well passengers and crew; their stools should be disinfected with a solution of sulphate of iron, and at once thrown into the sea; and all soiled clothing should be burned or thrown overboard. But if cases occur after the first four or five days out from port, it is safe to conclude that the vessel is the source of infection. Any suspected baggage should then be disinfected, and, for ten or twelve days, all water used on board should be boiled before being served out.[1] Experience teaches that a cholera-infected house, or ship, ceases to impart the disease after about twelve days, unless a new crop of the poison be introduced. An outbreak of cholera on shipboard can certainly be stamped out, and it is possible to do so during the passage of a steamship from Europe to America.

The foregoing suggestions can be carried out by any master who possesses sufficient intelligence to navigate a vessel, and it is believed that by imparting such definite information to seafaring men, commerce will be relieved from most of the restrictions reasonably imposed by quarantine. The *unreasonable* hindrances imposed by quarantine can only be corrected by cutting loose from senseless traditions and theories. It is unreasonable, as it is impracticable, to apply a theoretically uniform quarantine to all places, without reference to climate, the relations of surrounding countries, or the natural history of the disease to be combated. The question should be settled, separately and practically for each country or place, by taking into account the liability to infection of the port of destination, the period of incubation of the disease, the length of time consumed in the passage, and the measures enforced by the vessel *en route*. True quarantine measures should commence as soon as the vessel has left an infected port, and, if commercial people find that their well directed efforts are recognized by the port health-authorities, a strong incentive to rigid cleanliness will be thereby at once established, infectious diseases will be measurably restricted in their course, and the problem of quarantine will be made comparatively easy of solution. The practice of medical inspection and sanitation, as adopted and now carried out by Dr. Vanderpoel, at the port of New York, expresses the practical application of our present knowledge of cholera and yellow fever, as found applicable at that port.

If, upon arrival from an infected port, it be found that a vessel is clean, and that no case of sickness has occurred on board during her voyage, any detention of passengers and crew beyond the time required to thoroughly air and disinfect their baggage and dunnage, is believed to be unnecessary, provided that the period of incubation of the disease has passed during the voyage. If cases of *yellow fever* have occurred during the passage, the passengers and crew are removed from the vessel; the sick, if any, placed in hospital, and the well detained in a comfortable, healthy place, until five or six days after the occurrence of the last case, when they are allowed to proceed to the city. Meantime the vessel is at once subjected to a thorough airing and fumigation, and the cargo transferred to open lighters in the bay, by men kept for the purpose. During the unloading, the vessel is daily fumigated, and, when the transfer is completed, every available part is cleansed with water, and, after a thorough disinfection and fumigation, the vessel is returned to commerce. It is not found practicable to lay down arbitrary rules in regard to vessels on which *cholera* has occurred. Each vessel is judged by the particular features

[1] Plan recommended by Macnamara.

which belong to it. If prompt and energetic measures be enforced at the first appearance of the disease, its spread can be cut short, as before stated, and when this has occurred on vessels coming from Europe, it has been found practicable to allow the vessels, passengers, and crew to proceed to the city with only such delay as has been required to definitely ascertain the facts, and to perform disinfection. A vessel arriving, however, with cholera on board, the same precautionary measures are carried out as are enforced on the arrival of ships with yellow fever, and eight days after the occurrence of the last case, the passengers are allowed to leave. While the foregoing measures are necessary at New York, England wisely confines her supervision of cholera, from without, to the removal and care of the sick, and the cleansing of the vessel. It would be futile for England to quarantine against ports of the continent, with which she is in daily communication. Mr. Simon has truly said that "contraband of quarantine, like ordinary smuggling, is developed so soon as the inducements for it are considerable." Yellow fever is less liable to find lodgment in England than in Spain and Portugal, or in New York.

As it is the custom for many emigrants, bound for America from the continent of Europe, to embark at Liverpool or other healthy ports, when cholera prevails on the continent, this country is exposed to the introduction of the disease through the personal effects of such emigrants, sailing on healthy vessels from healthy ports. In a recent report to Congress, I called attention to the necessity for "prompt and authoritative information to threatened ports [of the United States] of the shipment of passengers or goods from a cholera-infected district," and suggested that the consular officers of the government should be instructed to place themselves in communication with the health-authorities of their respective localities, and to advise promptly, by cable, of the outbreak of cholera, and the sailing and destination of any vessels carrying passengers and goods from infected districts. By this plan (which the Honorable Secretary of State deems it practicable to carry into effect, if Congress provide the necessary means) the thorough disinfection of infected articles would be insured, and the danger from this source of infection would be lessened.

In considering the value and practice of disinfection, the fact should be kept in view that disinfectants are not as much needed as is cleanliness; where the latter prevails, the former are not required. It is when there is not time to get rid of filth, or when the poison has found lodgment, that disinfectants are applicable, and then their application should be thorough. The value of the several disinfectants is recognized, but their use on ships depends chiefly upon the manner of application. Ordinary fumigation cannot be relied upon to destroy the poison of an infected vessel, without removing the cargo, as has been exemplified in many instances, notably in the case of the bark Valparaiso, before cited. Dr. Perry[1] has devised an apparatus, which he used successfully at the New Orleans quarantine, in 1874, whereby either sulphurous-acid gas, carbolic-acid vapor, or heated air, can be forced into a ship through flexible rubber pipes, by means of blowers propelled by steam, all hatches and other openings in the ship having been first securely closed. Whether

[1] Effectual External Sanitary Regulations without Delay to Commerce. By A. W. Perry, M.D., of New Orleans. American Public-Health Association's Reports and Papers, vol. i. p. 437.

this process, in which are employed from thirty to one hundred pounds of sulphur, for a single vessel, will always prove effectual without removing the ship's cargo, remains to be determined by further trial.

It must be admitted that the germs of infectious diseases may elude the most vigilant sanitary supervision of shipping which can be devised; hence the importance of municipal co-operation, to the end that all exposed cities may, through wisely directed sanitary measures, be rendered less susceptible of infection. The value of sanitary supervision of ocean-travel and traffic, and of preventive measures at home, is more and more recognized by civilized nations, and the enlightened and vigorous prosecution of these means gives hope of rendering exposed countries less liable to infection; but the repeated battles against cholera and yellow fever should awaken an *international* spirit, and a determination to carry the war upon these diseases to their endemic homes, and to there instruct the people, and if need be compel them, to employ rational means of prevention.

From what has preceded, the following conclusions appear to be justified:—

I. The supervision of ocean-travel ought to be directed to securing good sanitary conditions for vessels at all times, out of as well as in port.

II. A system of Port-Sanitation should be adopted and administered for each country or place, separately, and should be modified in particular cases by taking into account the liability of the port to infection, the period of incubation of the disease, the length of time consumed in the voyage, and the measures enforced by the vessel *en route*.

III. In some countries, the detention of passengers and crews of ships hailing from infected ports is warranted, but for such time only as is necessary to complete the period of incubation of cholera or of yellow fever, counting from the date of departure from an infected port, or of landing from an infected vessel; in no instance should passengers or sailors be held for observation on board an infected vessel, and such vessel should not be detained beyond the period required for inspection, and for thorough disinfection and cleansing.

IV. Recognizing the fact that the morbific causes of infectious diseases may sometimes elude the most vigilant sanitary supervision of shipping, the importance of wisely directed internal sanitary measures can scarcely be overestimated.

V. As far as America is concerned, it is desirable that prompt and authoritative information should be had of the shipment of passengers or goods from districts infected with cholera or yellow fever, thereby insuring the thorough disinfection of infected articles.

VI. The endemic homes of cholera and yellow fever are the fields which give the greatest promise of satisfactory results to well-directed and energetic sanitary measures, and to this end an international sentiment should be awakened, so strong as to compel the careless and offending people to employ rational means of prevention.

Discussion on Dr. Woodworth's Paper.

After the reading of the preceding paper, Dr. A. S. Baldwin, of Jacksonville, Florida, said:—In the port where I have lived for the last thirty years, there has been no visitation of yellow fever as an epidemic. Isolated cases

have presented themselves, but there has been no spread. In one instance, the disease was brought in the contents of a valise. A gentleman, a resident of that section of country, had been visiting in Havana, and in the course of his rambles had passed through the Yellow-Fever Hospital. In a valise, which he had opened two or three times on the way, the disease was carried, and affected a nephew and niece who met him on his return. The niece recovered, but the nephew died, and a *post-mortem* examination showed the liver to be of a boxwood color. No other case of yellow fever followed from that outbreak. In 1857, a disease broke out in Jacksonville, supposed to be yellow fever, but it could not be traced to any foreign cause, and it differed somewhat in its symptoms. During the summer a marsh had been cut off, and a railroad depot erected thereon. This was in June. On the 20th of August, an individual living near the marsh was affected with a fever; on the 20th of September, the disease was still existing in that neighborhood, and had occasioned much alarm, 100 deaths having resulted. But the fever was as unlike the cases of yellow fever which have been brought to Jacksonville, as typhoid fever is unlike typhus.

Dr. Henry Hartshorne, of Haverford College, Pennsylvania, said:—If we believe that yellow fever is not personally communicable, there should be no detention of the sick at quarantine. In regard to cholera, the fact mentioned in the paper that persons escape by fleeing from the disease, is a proof that it is not more communicable than yellow fever. Efforts to disinfect the stools of patients have notoriously failed to arrest the disease, while local sanitary regulations have in this country prevented its spread. Quarantine and detention have caused many deaths on infected vessels. What is wanted, is to do away with personal detention at quarantine, and to see that sanitation is enforced at sea and in port. A comparison has shown that rigid restrictions have failed in Pensacola, while, in New York, less rigid restrictions have been attended with better results.

Dr. S. Oakley Vanderpoel, of New York, said:—There are three distinct schools of belief, as to quarantine: One relies wholly upon a certain amount of detention, and with another, everything depends on cleanliness, following out the English hygienic system by which quarantine has been done away with. I think that the modern school is the best, which employs a combination of moderate detention and sanitation. I am willing to go as far as any one in praise of local sanitation, but there is a necessity for the detention of vessels coming from infected ports. I say too that yellow fever is not contagious, from person to person, but I think that persons should be detained until the period of incubation of the disease has passed. In New York there is no *quarantine*, that is to say, no forty days' detention, as the name implies; there may be a delay of a couple of days, but the period of incubation must be allowed to elapse before passengers' baggage and clothing are permitted to go into the city. There have been several instances in France in which disease has been carried away to the country in clothing. A Savannah steamer came into New York Harbor last Sunday morning. The crew and passengers were perfectly well, and the vessel had not been lying in that portion of the town in which the epidemic was raging, but I held the vessel twenty-four hours, to make up the five days out. I do not call that a quarantine. Quarantine has killed more persons than it has saved. The epidemic in New York, in 1856, was caused by the Health Officers placing a vessel with its cargo off Long Island. Exposed to the sun, and lying there for twenty days, it became a pest-ship, and soon from 150 to 200 vessels were strung along the Long Island coast, all infected. Clothing and offal were thrown overboard from these, and people living within two or three miles of the coast suffered. In relation to cholera, I believe that if the dejections can be disposed of immediately, the risk of contagion can be prevented. There is a period of from one and a half to two hours, in which the dejections are inert; after that, fermentation sets in, and they become contagious. As far as I have been able to study the subject,

cholera can be traced along the lines of travel. Even with the same atmospheric conditions, five or ten miles from the line of travel, the disease is not found. There are seasons in which epidemics are intense, and others in which, if proper sanitary precautions be taken, cholera, though breaking out with great virulence, will last only a week or ten days.

Dr. J. G. Kerr, of San Francisco, said:—In the cities of China there are no municipal governments, and no arrangements are made for cleaning the streets. The filth which accumulates remains in the streets until carried off by natural processes, or carted off by scavengers. Some streets are filled the whole year with filth. I witnessed two epidemics of cholera in China, but they did not seem to be influenced by the filth, nor confined to the filthy sections. Why is this, when so much stress is placed in America and in Europe on cleanliness? My own opinion is, that it is due to the absence of underground sewerage. In the cities of China there is no system of underground drainage, and the gases which form are not confined. Epidemics there are not worse than here. The poisons which propagate these are fostered by the arrangement of drainage here, and fermentation in sewers is as much to blame as anything else. In China, where no attention is paid to drainage, there is no confinement of gases, and no concentration of influences which produce disease. My observations were confirmed by a physician of the British Army, who, during the Chinese war of 1856–1857, visited cities where the accumulations of filth were obnoxious to strangers.

Dr. Hartshorne said:—It can be easily seen that scattered filth is not as poisonous as when it is concentrated, but the fact still remains that filth is one of the factors of disease. If it be true that the period of incubation of cholera is short, yet I have known cases in which cholera has appeared when a vessel has been two weeks at sea. The morbific agent which produces cholera has met a vessel out at sea, and though the ship has been detained in quarantine, yet in all that time the disease has not passed to the cabin-passengers, showing that it is connected with local conditions and migratory causes.

Dr. Vanderpoel said:—I agree with Dr. Hartshorne that cholera has appeared in vessels hailing from perfectly healthy ports, but inquiry has shown that the steerage-passengers, among whom the disease has broken out, did not belong to the port from which they started. For instance, most emigrants to this country start from Liverpool, yet they belong to Poland and other places. These outbreaks on vessels have thus been traced to sections in which the disease has been raging. In the clothing of these emigrants, there is undoubtedly a large quantity of soiled linen, which, as is well known, carries the disease. The fact of the vessel coming from a healthy port does not show that every one on board belongs to the healthy port. I can account for what Dr. Hartshorne has related, by the baggage being closed until the vessel has got out to sea; case after case has been traced to trunks. That is one reason why the disease does not go among the cabin-passengers; steerage-passengers generally keep their baggage about them, while cabin-passengers have their trunks stored in the hold, and there they remain until the end of the voyage. Besides, the cabin-passengers are more cleanly, which is another point in favor of Dr. Hartshorne's idea of sanitation.

Dr. Ezra M. Hunt, of Metuchen, New Jersey, said:—I remember a case in which a lady visited a hospital, and three weeks afterwards wore the same silk dress which she had worn while at the hospital. Scarlet fever broke out immediately afterwards. As to filth, we have never yet had it proved to originate cholera. We understand that filth is a nest for disease, some of which it does, and some of which it does not, originate; and this is a good reason why we should get rid of it. The fact that it does not originate cholera and yellow fever, does not weaken the importance of not letting their contagia get into the filth. To prevent the spread of these diseases, we must stop baggage and disinfect vessels, and stop passengers too, if necessary, but not keep them on the ships.

A UNIVERSAL PHARMACOPŒIA.

BY

EDWARD R. SQUIBB, M.D.,

OF BROOKLYN.

The idea of an International or Universal Pharmacopœia, though by no means new, has within a few years past come before the medical and pharmaceutical professions with more than ordinary prominence, and much has been written on the subject. The rate of progress in the art of medicine in its utility to mankind, depends largely upon accumulated experience; experience is the result of research and observation; and the value of an observation is in direct proportion to its accuracy and completeness. That classification and comparison of observations, the result of which is experience in the art, depends largely for its value upon the uniformity of the conditions under which the observations are made, and hence the present strong tendency to control and to formulate the conditions under which experience accumulates, so that a larger proportion of it may take the rank of absolute knowledge. For example, we know, as the result of observation which has passed through the stage of experience to become absolute knowledge, that opium relieves pain. This reaction between opium and pain involves two distinct series of phenomena, or is conditioned from two separate bases: First, the cause, nature, and quantity of pain, and this concerns the pathologist; and, second, the cause, nature, and quantity of the opium appropriate to the reaction, and this concerns the therapeutist. Pain is universal. Opium has, through knowledge, become almost universal. To formulate and condition the opium for this reaction upon the best results of general experience in the past, so that future experience may accumulate under uniform conditions of the medicinal agent—and may accumulate universally to the same single end, namely, advanced knowledge for universal good—is the object sought for in a Universal Pharmacopœia.

Some such train of reasoning as this, having for its basis, at least, the establishment of a universal standard of strength, composition, and quality, for medicinal agents, so that by accuracy in the agents the results of their use all over the world may be compared with accuracy, and thus more rapidly convert empirical experience into knowledge, has been generally advanced in support of the design. And it may be said that the same line of argument, and the same necessities which made National Pharmacopœias first useful, and then indispensable, must, with the advance of civilization, apply with equal force to produce an International Pharmacopœia. Thus the advantages to be expected from a Universal Pharmacopœia are so great and so easily shown, and the arguments for it are so forcible, that up to this time all writers upon the subject, as far as seen, in all nations, have been on one side of the question. And yet, although ranged on the same side of the question, I have, by thoughtful consideration of the subject, gradually reached the conclusion that the design is premature, and for the present age impracticable, for the following principal reasons:—

(1) The difficulties of constructing a Universal Pharmacopœia, which would be universal in any true sense, would probably be at present insurmountable, because, as in other international designs of a similar character, the present national standards are so very different that they could not be made to harmonize without radical changes, which the standard of medical education of the age is not high enough to admit; and because each prominent nation would at once seek to make its own pharmacopœia the basis to which others should be changed, as the condition upon which it would share in the undertaking, just as is done at present in the attempts to unify the coinage of different nations. And if a Universal Pharmacopœia should be constructed, with one or more prominent nations omitted from active co-operation, it would be but a sham, and would in the end be productive of more harm than good, since anything of the kind which might not be thorough and sound, would not stand, nor be authoritative, and would but add to the present confusion. The complete idea of a Universal Pharmacopœia is, of course, that it should take the place of all national pharmacopœias, and render these unnecessary, so that they should be abandoned. But short of this, there seems to be a popular idea which aims to embrace in the design only the making of the preparations, or the compound medicaments whether chemical or galenical, of a uniform strength and character, leaving the national pharmacopœias to be as necessary as ever, but to be in accord in regard to the strength and quality of the agents of certain classes of remedies which have been long and commonly used in different nations by the same or similar names. For example, colocynth is used under the same name in all the national pharmacopœias, but its preparations and compounds in the different pharmacopœias, under the same or similar names, contain it in very different proportions. To have such preparations and compounds of the same strength, and to have them designated by the same name everywhere—and this only—leaving the national pharmacopœias as they are with such exceptions of common accord, seems to be the less complete idea of a Universal Pharmacopœia aimed at by some writers. But this really involves no less difficulties than the complete idea, nor are the difficulties of a different character, nor more easily overcome. For the primary substance itself must be uniformly defined or described, or otherwise it may vary so much in different countries and markets as to make its preparations and compounds as different and as variable from that cause as they would be from different proportions.. And all primary substances and chemicals would require the same definition and description in order to secure their uniformity in use. Hence the difficulties in making a Universal Pharmacopœia seem to be insurmountable in the present age. But let it be assumed that a proper commission or council could be had, and that the great amount of time and labor needful had been given to the work, and that it had been harmoniously completed to the entire satisfaction of all nations; even then, unlike coinage, and weights and measures, it could not be considered as either established or completed, since in order to carry out the idea, and preserve its utility, it would have to be revised at short intervals, and the commission would have to be reconstructed from time to time, or would have to be permanent.

(2) To have a Universal Pharmacopœia, involves the idea of universal applicability. Could it be made universally applicable, or universally useful? In civilized countries the civilization is not uniform in degree, and between nations there is a still wider difference in this respect. All the normals of different nations differ, that is, geographic position,

climate, race, food, clothing, manners, habits, etc., make nations differ so much that their health and their diseases are not the same either in cause, course, or result, and are therefore not subject to uniformity in management or treatment.

(3) Again, the standard and degree of medical education is anything but uniform throughout the world, and therefore a uniform code for its use might not be generally applicable, any more than a universal grammar would be applicable to popular use in all languages.

(4) Finally, all modern progress in the medical art points unmistakably to singleness and simplicity in medicinal agents, and in their application. The older and more complex formulas are rapidly passing out of use, and single substances of more or less known physiological power, and of definite constitution, are as rapidly taking their place in the only true and permanent interest of the art; because upon such medication only can much accuracy of observation be claimed. Then, just in proportion to the progress in this direction, does a Universal Pharmacopœia become less necessary and less useful. And by means of this progress, the idea of a Universal Pharmacopœia becomes year by year more easily carried out, because simple substances of definite constitution and established character and power are perhaps alone applicable to universal uses, and because such are easily defined, described, and controlled.

These apparent difficulties in the way of a Universal Pharmacopœia are presented with hesitation, because the offering them may be construed into opposition to a design for improving the means whereby precision of observation and of result is to be looked for. The suggestions are made, however, in no such spirit, but simply to present a few points which may serve to awaken thoughtful attention to that side of the question which has not hitherto been sufficiently considered.

THE RELATIONS OF THE PHARMACIST TO THE MEDICAL PROFESSION.

BY

EZRA M. HUNT, M.D.,

OF METUCHEN, N. J.

The relation of Pharmacy to Practical Medicine is not merely collateral, but to the extremest degree radical and essential. All the commandments that form the decalogue of the physician find their summation in two avowed purposes. One is thoroughly to make out the disease, and the other is thoroughly to make out the remedy. Anatomy, physiology, and pathology, mean little to us professionally and practically, unless thereby we establish standards for the normal and abnormal, and by comparisons and observations are able to arrive at a diagnosis. Diagnosis means but little unless it defines, and differentiates, and knows, in order to guide to correct treatment. But treatment is as impossible without accurate pharmacy, as is diagnosis without accurate physiology. Indeed, the term diagnosis is as applicable to Materia Medica as to Disease. It is just as indispensable to know through and through a medicine, as it is to know thoroughly a disease. If there is failure at all either in the one or in the other, we have, as far as ignorance can accomplish it, an absolute failure resulting, just as if both were alike defective. A polished steel bar on one side, elaborately finished and laid, and a tarred cable-rope on the other, never yet made a railroad track. None the better will there be efficiency in conducting onward this great science of ours, with elaborated diagnosis on one side, and a smeared pharmaceutics on the other.

I am quite aware that in what may be called popular medical feeling, diagnosis of a disease outranks diagnosis of a remedy. There are a glow and an enthusiasm about anatomy, histology, physiology, and pathology, because of the subjects themselves, and of the accuracy of classification of which they admit, but which has not as yet its parallel in the corresponding department. A human being is so much grander a thing than a poppy-seed, that it is much more attractive to pry into the cells and functions of the one than into those of the other. The old story of the Frenchman, who in his hospital rounds thrilled his pupils by his accurate demarcations between healthy and diseased action, is still pertinent. When asked the remedy, he turned away with a shrug, as if that was a matter in which he had no concern. Until with equal identification and elaboration he had indicated this, he might be anatomist, histologist, physiologist, and pathologist; but he could not be a physician.

The anatomy, histology, physiology, and pathology of the Materia Medica must be studied individually and accurately, just as we study the subject Man. If, in a certain sense, the one is to be investigated as if the question of treatment would never occur, so the other may be studied as if the drugs concerned were never to be employed as remedies. Such at least may be the tendency of the naturalist, in either department. But

he must know that his studies, as thus pursued, are merely preliminary or collateral. His relations to medical practice (when he stops here) are only those of the botanist, geologist, chemist, or comparative anatomist. Our practice, our profession, our art, has as its sole object our ability to make such an adjustment between the individual, corporeal man, and the substances found in nature outside of him, as will promote his healthfulness. This, and this only, is the practice of medicine.

Therapeutics, since it is the application of remedies to the cure of disease, is almost a definition of the art of medicine. Dunglison defines a therapeutist as "a practitioner of medicine." Watts is only a little more general when he says, "Medicine is justly distributed into prophylactic, or the art of preserving health, and therapeutic, or the art of restoring it." Let it then be axiomatic with us that none but a therapeutist is a physician. The knowledge of the remedy in all its accuracy and in all its effects, is as essential as the knowledge of disease. It is the conjunction that marks the inflowing tidal-wave of medical knowledge, and that bears with it the skilful practitioner. So fundamental and essential is the concurrence of these conditions of medical art, and so palpable the proposition even upon its mere bare statement, that we can scarcely account for the existing contrast and discrepancy between the prominence given to the study of disease, and that tendered to the study of remedies. Handfield Jones wrote to me some time since, in a private letter, "a more perfect knowledge of the action of remedies is the great desideratum of the day."

A recent prize essay of the New York State Medical Society (1862) had this as its motto: "Physiology has become a science by well-conducted experiments that have illustrated facts. Can therapeutics claim to be a science while so many of its votaries are content with assertions, without experimental facts to support them?" We must at least affirm that unless therapeutics be a science, physiology cannot make the practice of medicine an art. This necessitates as a basic condition, not only of success but of all experimental investigation, a certified reliability in the articles by which our therapy is tested and applied. What we need just now, is the most accurate assemblage and classification of experimental and experiential facts as to medicines themselves, and the greatest safeguards as to purity and uniformity, in order that with scientific exactness we may trace and record their actions. Accurate study and adjustment here are very difficult to secure, as is almost everything of value in our art. But only thus can that exactness of result be obtained which will make real treatment not only possible but actual.

I have said thus much as to the general significance of therapeutics, and its essential foundations, in order to magnify and emphasize this fundamental condition of the progress of rational and practical medicine.

Our definiteness must begin with definiteness as to the disease which we have to treat, and definiteness as to the medicines which we propose to use. To this end, uniformity of preparation and reliability of dispensation must accompany a definite knowledge of what we have a right to expect from the quantity of each article named in our prescriptions. How absurd that we should seek for and watch the action of a preparation, and expect and record salutary results from its use, unless the preparation itself be of an indisputable character. Thus it needs no argument to prove that the relation of what is called Pharmacy to the Practice of Medicine is vital. It has so to do with the essence of the thing, it is so much the centre and substance of our professional science

and art, that it is an accessory before the fact. It will not do to assign it to a territory adjacent to that of the medical profession. Such border land is always doubtful land. As well might I recognize my right foot or my right hand as an acquaintance: my only real prospect of material success is to recognize and have them a part of my integral self. Nay, the case is even stronger: it is wearing one of the vital organs outside of the body, to put the framers and formers of our remedies totally without the pale of our profession. Their department must have fundamentally the surveillance of the medical profession, and this can only be secured by its being within the adjudication of the faculty. Other assurances of competency may be occasional and accidental, but only this can be reliable, when the two branches of science are so closely connected. When seeking aid in our diagnosis, we consistently go to him who, while belonging to our profession, may have made of one department a specialty. When he puts himself outside the pale of the profession, or is so put by circumstances, whatever his boasted attainments, we recognize that it is not for our interests, and still less for the interests of medical science, that we should avail ourselves of his assistance. Yet for aid in the department of therapeutics, that other arm of the profession, a very great part of our dependence is upon those who are outside. The relation is a purely commercial one, and tempts to demoralization. No profession can ever put so much of its practice, of its essentials, so totally outside of itself, and yet conserve its best interests as a science or an art. The effect always will be to enfeeble the practitioner as to his knowledge of remedies, so that he will not even know how to adjudge competency, or to verify the assurance of reliability and accuracy, while another effect will be to make the dispenser a mere tradesman.

The first step in remedying this evil must be to hold pharmacy to accountability and reliability, by making it a part of the profession of medicine. It must be a specialty, like every other medical specialty, having its foundation in a thorough medical education. It must, like ophthalmology and gynæcology, be made a specialty, only because it may not be practicable for each practitioner to attend to every department of medicine, and in order that by giving more time for study greater accuracy may thereby be attained.

It is a noticeable fact, in the history of medicine, that this was just the position that pharmacy formerly occupied. It was made a specialty not that it might be a trade, adjunct and accessory to, yet outside of, medical art, but because it was so fundamental and essential as to require concentrated study within the field of our calling. Even the English method at the present day shows how thoroughly the Apothecary's business was identified with the medical profession. It was so fundamental and integral as to give name to the practitioner.

The results of the separation which has occurred are so patent as to be undeniable, and so degrading as to be notorious. The average American dispenser is a dry-grocer, who avails himself of the patronage of the medical profession in order the more to thrive as a merchant of drugs, dye-stuffs, prescriptions, wares, patent medicines, fancy articles, liquors, and manifold incidentals too numerous for cataloguing. The price-current, for instance, of a prominent New York drug house, in over two hundred pages, has only about forty devoted to drugs, and only one-half of these are used medicinally. Not a few bear testimony that their largest transactions are in patent nostrums, in which many of them have a proprietary interest. The retailers differ very much as to their stock in

trade according to locality; and in that part of their business which is pushed into prominence we know of but few who follow what from the medical, professional stand-point would be considered in accordance with the rules of ethics. Under the elegant college-building of one of the best of American medical schools, the pharmacist posts his own cure for neuralgia, and prepares his own specifics for diarrhœa, and is at the same time well patronized by the profession with prescriptions.

As the word from which "apothecary" is derived, means a repository or storehouse, and as "drug" is a general name for commodities employed for the purposes of medicine, dyeing, tanning, and other uses, these dealers may be excused for their employment of the terms, and may become general storekeepers. We do not object that honorable men should pursue as a legitimate business the sale of this combination of commodities, which the law permits. Our claim is that the preparation of medicines, and the dispensing of the same by physician's prescriptions, should not by the physician be tolerated under such an arrangement. Medical practice is demoralized by such association, and an incubus is thus put upon the real advancement of therapeutical knowledge among practitioners.

The only question before the wholesale dealer, is how to carry on his trade to the best pecuniary advantage. If he acquire any pharmaceutical knowledge at all, it is not in the interests of legitimate practice, but that he may associate this with the other branches of the trade. We know of a leading house which pays a practising physician to acquaint it with the tastes of the profession, and to inform it of what is most likely to please. The laxness of the retailers, if not quite so outspoken, is often no less real. Prescribing pharmacists abound. The prescriptions of physicians are used with freedom, and are repeated indefinitely without the knowledge of the prescriber. If in some stores the patent-medicine notices are not so prominent, the article is nevertheless kept in stock, and large sales of it are made.

We are aware that there are three classes of pharmacists: Those of the first, and by far the most numerous class, do all in their power to generalize their business, having not the least regard for the physician, except as a customer, and availing themselves with equal suavity of Jacob Townsend and of Austin Flint. Those of the second class desire the patronage of the profession more than they do a general business; they have a faint perception of the higher sphere of therapeutics, and so foster a prescription business, while feeling themselves necessitated to keep all things required in the general trade. We theoretically add a third class, of those who deal only in pharmaceutical preparations, and who dispense medicines within such bounds as a profession can recognize. But we add this class simply because many of the best of our pharmacists wish that it existed, and that they belonged to it. It is quite plain that while deploring the present state of things they do not see any way to improve it.

At the last meeting of the American Pharmaceutical Association, Professor Maisch spoke of the immense traffic in patent medicines. The Association professed to be opposed to the sale of these articles, but it is added "the efforts of pharmacists in this direction would amount to nothing, as long as patent medicines are called for by the public." Nothing could more plainly show the present status of the business. We might just as well say that the physician is compelled to prescribe patent medicines because they are popular with the public. It is merely the forced admission that the pharmacist does each day that which is antagonistic to the principle of individual prescription for each case.

And we do not notice any gain in the adaptation of the drug business to professional ethics. A recent New York authority[1] says that in that city "the sign, 'Physician's prescriptions accurately prepared,' is flanked on all sides by cure-all pills, wonderful lotions, and infallible pain-killers." This is even more literally true in all the smaller cities and villages through the land. I have purposely examined some of the leading so-called pharmacies between New York and Philadelphia, and have found the evil magnified beyond expression. I do not suppose that it will ever be possible to break up these bric-a-brac shops, or prevent the mongrel sale. Public demand will cause a place of supply. Stores will ever continue to exist, at which, under the name of "apothecary," stationery and innocent toys, perfumery and cosmetics, soda water and liquors, blacking and garden-seeds, soaps and paints, window glass and putty, and all varieties of patent medicines will continue to be vended. Let the drug-grocer go on, and be recognized as such in his business, but let not such be the place to which we resort for the compounding of our prescriptions. If we give recognition to such establishments, we must not be critical because these bazaars are the points of departure from regularity in medical practice. Quasi-elixirs and counter-doctors' prescriptions are the inevitable results of such afflictions. Worse still, the public is educated into low views of our art, and among physicians themselves the relations of therapeutics to practice are distorted. Manifold preparations are smuggled into professional use, which would not get there under proper medical supervision, and such pharmacy is in turn the progeny and the progenitor of lax therapeutics.

We are not to expect that any radical reform will originate with the apothecaries themselves. Their relations to our profession being merely of a business kind, there are not sufficient motives for change amid the various mercantile interests pointing in other directions. We are told of late, on the best of authority,[2] that there is danger that the United States Pharmacopœia itself will go over "to the commercial interests of pharmacy." Prof. Remington, in his address before the Philadelphia College of Pharmacy, March 14, 1876, in view of the present degraded tendencies of pharmaceutists, says: "Do you regard your avocation as a profession, or as a mere business calling? . . . What shall it be? Profession or trade, pharmacy or black art, pharmacopœia or price current?" The very character of the business decides that question for us, and decides too its reflex influence on medical science and practice. Definite and damaging results must flow to us from such untoward channels of communication with the populace. It is not surprising that the vender of patent medicines should himself become a compounder and prescriber, and that those whom we send for prescriptions should be beguiled by the beautiful signs, or influenced by the advertisements of nostrums, with which they meet.

For all this condition of things I hold the medical profession, in a great degree, responsible. I do not complain of the American druggist that, placed by the consent and really by the action of the medical profession outside its guild, he should accept the situation and assume his relations to that profession to be merely commercial. I will not blame the College of Pharmacy of the city of New York,[3] whose business it is to educate successful venders of drugs, that its Code of Ethics says that the "necessities of the times" warrant the keeping of patent medicines, although

[1] Medical Record. [2] E. R. Squibb, Ibid., July, 1876, p. 691.
[3] Ibid., Oct. 30, 1875.

it declares their sale to be "not a legitimate part of our business custom." But I do complain that our profession, by complicity with this system, aids and abets a calling which, by its very construction and methods of practice, compromises that profession, militates against scientific medicine, lowers our own estimate of therapeutics, and tends to remove the care of our curative forces outside the domain of our professional jurisdiction. The medical profession in New York City regards it as so improper for a licensed practitioner to carry on the business of a retail druggist, that it excludes such an one from medical societies, and will not place his name in its register. If a physician cannot keep a modern pharmacy, *as certainly he cannot* consistently with proper professional feeling, I do not quite see how he can suitably patronize one. It would be well if it were practicable for every physician to refuse to send prescriptions to be compounded by any save those duly licensed in medicine, and who, having chosen this as their specialty, were bound in ethical propriety not to prescribe, to sell and to compound only in recognized pharmacy, and to hold themselves in the same relative position as a part of our profession, as do others who pursue a particular branch.

If, to-day, ten pharmacists in such cities as New York and Philadelphia could be brought into this direct association with the profession, it would be a gain for pharmacy and therapeutics of the most reformatory and indisputable character. Such a relation, existing between one or more of our leading manufacturers and the medical profession, is an elevation of the whole domain of therapeutics, not because of their personal attainments merely, but because they are thus held thoroughly responsible to those high therapeutic demands which are alike in the real interests of each department. When we bring the same conditions to bear on the retail dispenser, we shall have our greatest security for the purity and adaptability of medicines. All hope of reform from outside is Utopian, because the organic relation is wrong, and must first of all be righted.

A method of this kind needs only to be initiated by such a medical school as that of Harvard, by such a State Society as that of New York, or by such a school of pharmacy as that of Philadelphia, in order to make of it an ultimate success. Enough of the better class of physicians would rally to the support of those of their own number who should thus thoroughly identify themselves with the interests of the profession in one of its specialties. Many a pharmacist, sighing for deliverance from his present mongrel trade, would gladly accept his place in our profession, and in this branch of it would contribute to its welfare. All chemical and microscopical examinations, and various similar aids which the general practitioner now seeks and pays for, might naturally be committed to this branch of the profession, as well as much that is now appropriated by the instrument-maker. Place the dispensary in its natural relation, in charge of a member of the medical profession by choice assigned to that department, and society would be shielded from exposure to irresponsible remedies, and from the temptation to self-medication to which, by the present system, it is constantly and cordially invited.

The pharmacist, within the fold where he legitimately belonged, would have the status demanded by therapeutics, and would thereby become directly interested with other physicians in the advance of our art. There would be hosts of apothecaries on the outskirts, just as now there are hosts of irregular practitioners on the outskirts of the legitimate profession, but they would recognize themselves as belonging to the open

frontier and the outside common. The line of demarcation would be so pronounced, and the professional recognition so honorable, that the real pharmacist and the real physician would alike rejoice. Therapeutics, adjusting the relation between diagnosis and cure, has the right to claim such a union. It already takes every one of us by the hand, and shows us that it is not meet that we should divorce from us that which forms an integral part of our profession, and which is incident to our very life-success. Instead of leaving the pharmacist outside, let us invite him within the boundaries of legitimate practice, and let him become imbued with the *esprit de corps* which belongs to a noble profession.

I am importunate in this regard, because I feel that the present method of supply, or the medium of communication between ourselves and our patients, as far as remedial agency is concerned, is essentially defective. If it were a mere criticism as to feasibility of method, or as to expediency of convenient or financial management, it could be passed by; but the whole success of treatment, and therefore the welfare of both patient and practitioner, are alike involved. The medicine or thing prescribed is the result and means of conveyance of expressed skill—the deliberate verdict on a case more or less critical. It is entitled to the most assuring safeguard which the profession itself can furnish. This safeguard cannot be furnished by adjunct relations. We cannot afford to leave the work of preparing our remedies to the manipulation of an outside corps. Identify pharmacy as fully with the profession as any other legitimately followed medical specialty, and we at once throw around it a *cordon* of protection and give an assurance of reform. Such vastness of uncertainty as is at present distributed from the drug-shops of our land, and very much under our prescribing, must be abolished; and this can only be done by reinstating pharmacy as part and parcel of our calling.

This is peculiarly essential to medical progress, because for the next quarter of a century the most crucial questions of practical medicine will centre in therapeutics. The two great preliminaries for our progress are (1) to have physicians record clinical and experimental results most exactly, and to tabulate in extended classifications the symptoms of disease, and (2) so to acquaint us with the physiological effects of medicines, and their effects in the various kinds and stages of disease, as to enable us in like manner to tabulate remedies. To do this, we must be assured of the precise quality, quantity, and precision of combination, of articles used, so that sources of error shall be indisputably eliminated. All of us who have examined and compared various specimens of medicines, know how much this means, and how much uncertainty is introduced into all chemical records by unreliable preparations. Never shall we be able to exclude this disturbing factor, confusing all statistics, until the prevalent system of dispensing medicines is changed, and until the pharmacist takes his place as a member of our profession, glad to be held strictly responsible to its ethics, and finding it to his interest to practise his specialty in the interests of every other department.

The following conclusions are offered as being warranted by what has gone before:—

I. The interests of society and of the medical profession render it desirable that the furnishing of medicines should be surrounded with greater safeguards.

II. There are reasons why pharmacy should be regarded as a specialty within the general bounds of the medical profession.

THE MICROSCOPIC STUDY OF THE BRAIN.

BY

WALTER KEMPSTER, M.D.,

PHYSICIAN AND SUPERINTENDENT OF THE NORTHERN HOSPITAL FOR THE INSANE, OSHKOSH, WISCONSIN.

The microscopic examination of the tissues of the brain has added so much that is new to the departments of anatomy, physiology, and pathology, that each demands more time for its consideration than can be given to it now. The microscopic pathology of the brain, as found in insanity, having engaged my attention more particularly, I shall devote myself wholly to this department of the subject.

Changes in the Meninges.—Insanity, in its various forms, is found to involve all the cerebral tissues. Of the membranes investing the cerebral mass, the dura mater is the least liable to general histological change, general paresis being the only disease in which it is found to be uniformly altered. The alterations consist of thickening of the tissue, the increase in thickness depending upon the formation of a new membrane, apparently due to a disease of the epithelium lining the dura mater; new vessels are formed in the membrane, generally tortuous and irregular. In the more advanced stages of the disease, minute hemorrhagic points are found scattered over the under surface, depending upon rupture of some of the most tender capillaries. This state of the membrane must be sought for particularly, as no great departure from the normal standard is observed without the aid of a lens, the most characteristic change being the presence of a delicate, pink tinge, not found ordinarily in the normal state. Transverse sections of the tissue, carefully prepared, will show this condition very perfectly; or the new membrane may be torn from the dura mater, though it cannot then be so well studied. The large hemorrhagic clots found sometimes over the brain surface, in general paresis, occur between the dura mater and this new membrane, the latter

separating the clot from the subjacent tissues, and forming a delicate film which, being stained by the blood, is often overlooked, and is removed when the membrane is torn away from the clot. Not unfrequently the dura mater is found thickened in localized patches in other forms of mental alienation, the increase of thickness appearing then to depend upon an inflammatory condition which does not differ essentially in appearance from that found in ordinary inflammation.

The arachnoid and pia mater are nearly always found diseased in all forms of insanity, the most prominent changes being found in the vascular system, and consisting of deviations in the course, size, and structure of the capillaries. The membranes are usually semi-opaque, and in some cases thickened, and in thickening of the arachnoid, granules and the products of inflammation are found upon its external surface. The deviations in the course of the vessels, consist of increased tortuosity; the deviations in size, of aneurismal enlargement; and the deviations in structure, of hypertrophy and degenerative processes.

In removing the pia mater from the convolutions, before the brain has been placed in any hardening agent, portions of the external layer of gray matter often adhere to the membrane, and patches of gray matter, varying in size from that of a pin's head to the entire width of a convolution, may be removed with it. In the parts so removed, it is common to find changes of structure, having their origin in abnormal deposits on the vessels, in minute hemorrhages, dependent upon rupture of vessels, or in passive exudation, preparing the way for inflammatory changes, and for softening and destruction of adjacent nerve-tissue.

The pia mater is composed of two layers, and in diseased states these layers are easily demonstrated. Occasionally we find a hemorrhagic point between the layers, in which case the layer on each side becomes thickened by inflammatory changes; the thickening of the membrane arrests the circulation in the contiguous parts, sometimes completely shutting off the blood-supply to that part of the convolution which is covered by the membrane, and, the twigs conveying the blood to the external layers of gray matter being first closed, causes local softening of the gray matter. The change here alluded to is often found in cases of general paresis, although it is also found in other forms of mental disease of an acute type. When the hemorrhage occurs between the pia mater and the convolution, secondary changes do not appear to follow so frequently. Occasionally, changes occur in the pia mater which do not depend on hemorrhagic points; the simple thickening of the membrane from inflammatory processes may cut off the blood-supply, and necro-biosis of the tissue beneath then results.

New material is sometimes found on the external layer of the pia mater, increasing the thickness of the membrane three or fourfold, and being always the result of inflammatory processes. It is rare to find extensive lesions in either the arachnoid or pia mater, without both membranes being involved, though the pia mater is probably the first affected; this is especially noticeable when pus has been formed, the pia mater being then seriously diseased and thickened by deposits of plastic material upon its surface.

Bloodvessels.—The most constant lesions observed in the cerebral tissue of those who die insane, are connected with the circulatory apparatus; and the first of these to be described, because probably laying the foundation for other lesions, is engorgement of the arterioles and capillaries. It will be remembered that the coats of the cerebral vessels are in their

normal state more inelastic than those of other vessels, and that their lumen is considerably larger than that of vessels of the same size elsewhere. In the earlier stages of insanity, there is often fulness of the cerebral vessels, resulting either from rapidity of the heart's action, which forcibly dilates the capillaries for a considerable length of time, or from stasis of blood, depending upon disease of the vaso-motor apparatus. If this fulness is relieved in a short time, the capillary resumes its ordinary calibre, but the second distension is more easily effected than the first, and the vessel is then less liable to resume its normal size. The process, if frequently repeated, leaves the capillary in a state of permanent distension. The vessel is then irregular in form, being larger above a bifurcation than below, and presents the appearance of having been stuffed. If the engorgement has been of long standing, changes in the coats of the vessel and in the adjoining brain-tissue will be seen. The change which occurs in the vessels is a fatty degeneration of the muscular coats, or of the cells constituting the walls of the finer capillaries.

The first change noticed in the coats of the larger vessels is the collection of numbers of fine granules, apparently lying on the wall of the vessel, or developed within its muscular coat; these are grouped together, the granular deposit varying in size according to the stage of the degenerative process. In the walls of the smaller capillaries, each cell maintains its contour at first, but is slightly increased in size. Granules are then formed near the nucleus, gradually encroaching upon the plasma of the cell, which in time becomes a mass of granules; the nucleus becomes involved in the same granular change, and finally disappears. In the arterioles the degenerative process continues until the evidences of muscular fibre disappear, and till the vessel looks like a mass of granular material, through which its outline can sometimes be dimly traced. A remarkable instance of infarction and secondary change, illustrating the fact that these conditions may occur *in utero*, was found in the brain of an infant who died in an epileptic convulsion immediately after birth. The mother had for years been epileptic, and during pregnancy had had repeated epileptic seizures, followed by paroxysms of violence. In the third left anterior convolution of this infant's brain, cysts were found, with fusiform dilatations of the vessels, and fatty degeneration of the walls and cells of the vessels and capillaries. One vessel occupied a place in a large cyst, wherein abundant evidences of new material, the product of inflammation, existed, and where absorption must have occurred.

A change which appears to depend upon over distension and subsequent relaxation is tortuosity and kinking; the deviation in direction ranges from a simple wavy course to the formation of a complete loop, as though a knot had been tied in the vessel. The tortuous vessel is not confined to any particular form of mental alienation, but exists in all forms in which distension and subsequent relaxation have occurred, and has been noted in acute mania, melancholia, dementia, and general paresis. I have not found the tortuous vessels in the brains of the lower animals, nor in the cerebral tissue of those who have died sane, except in the brain of a man executed for murder, and who had been insane some years before.

A condition that has given rise to considerable discussion in the department of cerebral pathology, is the existence of what have been called the "perivascular canals," in which the bloodvessels are found, and the "hyaline membrane" or "perivascular sheath," which surrounds the

vessel. The canal and sheath are not easily demonstrated in the normal brain, but in the diseased tissue they are readily observed. The membrane or sheath, as it is called, does not always envelop the vessel closely, but sometimes hangs loosely about it, and, where the vessel bifurcates, forms a triangular sac. Sometimes the sheath is found closely applied to the brain-tissue, this condition occurring where there has been excessive engorgement a short time prior to death, the sheath having been distended, and the brain-tissue crowded back. After death, the vessel recedes somewhat, leaving the membrane attached to the nerve-tissue, and the vessel itself adhering to one portion of the membrane; transverse sections show the vessel apparently lying in a tunnel, which is composed of the enveloping sheath applied to the wall of nerve-tissue. The vessel, partially distended with blood, is found in the canal, and tortuous vessels are sometimes found lying in comparatively straight canals.

The various conditions of the perivascular canal are best studied in fresh specimens, as we can thus acquire a better idea of the parts as they actually exist, all hardening agents causing some contraction of the tissue. Injected specimens, especially those of diseased cerebral tissue, will aid materially in studying these interesting conditions, but for tracing the ramifications of the canal, the hardened tissue answers best.

Lymph cells are found in the canal, in the fresh tissue, while smaller granular bodies glide over each other as pressure is made on the covering glass; it is the opinion of some Continental observers that these canals convey the products of waste from the cerebral tissue into a lymph space in the pia mater, an opinion which appears to be based upon good reasons, for the perivascular canal can be traced into the space between the layers of the pia mater. In all cases in which engorgement has existed for some time, crystals of hæmatoidine are found both upon the walls of the vessel, and also in the perivascular sheath. This deposit varies considerably in extent, sometimes occurring only at the bifurcation of the vessels (where it is always most abundant), and at other times completely incrusting the coat of the vessel, and thickly deposited upon the sheath. Another deposit which is found upon the vessel, much smaller than the crystals of hæmatoidine, appears as minute specks of a fatty character, varying in size from $\frac{1}{10000}$ to $\frac{1}{3000}$ of an inch in diameter; these are yellowish-brown in color, and under high powers appear crystalline, but they are not easily dissolved, nor are they affected in any way by staining fluids.

As a result of the excessive engorgement of the vessels, we have fusiform enlargements and miliary aneurisms. Fusiform enlargements appear to depend upon degeneration of the coats of the vessels, which sometimes rupture, when the blood is poured out into the perivascular canals, the hemorrhage being limited by the sheath; these limited hemorrhages are found only in the course of the smaller capillaries, where the force of the blood-current is not sufficient to burst the sheath after escaping from the vessel. This is not a frequent occurrence, but has been observed a sufficient number of times to make it noteworthy. These fusiform enlargements often extend to a bifurcation, the vessel again enlarging beyond until the next branch is reached, and so on to the finer capillaries. In all cases of fusiform enlargement, fatty metamorphosis, in varying degree, has been found. Miliary aneurisms are not as frequent as fusiform enlargements, but are more striking in appearance; they are larger, ranging from $\frac{1}{60}$ to $\frac{1}{25}$ of an inch in diameter,

and can sometimes be seen without the aid of a lens. The vessels upon which these aneurisms occur, do not appear to be as seriously diseased as those in which fusiform enlargements are found, but the aneurisms, too, depend upon morbid changes in the vessels' coats: degeneration of the walls (the *peri-arteritis* of Charcot), together with engorgement, appear to determine their existence in a certain number of cases, but other factors are concerned in their formation, as the aneurisms are not found in all cases of degeneration even though evidences of engorgement also exist. They are found in all parts of the brain-tissue, and in the membranes. I have found them in the gray matter of the spinal cord; in one notable case, the sac was situated near the origin of the first cervical nerve.

Hypertrophy and fatty degeneration of the capillaries are frequently noted in cases of protracted engorgement, this abnormal condition at times existing to such an extent as to destroy the vessel, the mass forming a nidus around which changes in the structure of the nerve-tissue occur. Occlusion of the capillaries sometimes results from stasis following engorgement, the minute thrombi being formed when the circulation is impeded. If the circulation of a bat's wing be arrested for a time, certain of the blood-corpuscles are seen to adhere together, forming minute thrombi. The agglomerated corpuscles are moved along with the current until they pass into a vessel of small calibre, where they finally lodge, generally at a bifurcation. The blood beyond the thrombus in the plugged capillary becomes stationary, and a clot results, secondary degenerative changes being then induced. In one case of acute mania, recently examined, these minute thrombi were found in great numbers, completely depriving large areas of the brain of their blood supply. The vessels beyond the plug are in some cases found empty, but in others distended with coagula, the adjacent brain-tissue being deeply stained with the coloring matter of the blood. When we recall for a moment the great vascularity of the brain, the effect of closure of the vessels must be regarded as a fruitful source of abnormal cerebral action, independent of the results which follow as a consequence of the deprivation of nutrition.

In cases of insanity of long duration, or where there has been serious disorganization of brain-tissue, a growth sometimes appears near the capillaries, projecting beyond the sheath into the brain-tissue; the growth is ovoid, one end being connected to the capillary. These growths are sometimes arranged in pairs, six or eight deep, the largest pair being at one end of the mass, and each pair being smaller than the preceding. They sometimes appear to surround the vessel, the outline of which appears distinctly in the mass. The edges of these growths are not sharp, and they do not have an investing membrane. The mass is granular, of a grayish-white color, and is not affected by carmine staining. There are no nuclei apparent, and although the nerve-tissue is destroyed wherever these growths occur, none of the *débris* caused by destruction of nerve-tissue can be found in or about them. They are not fatty, and there are no crystals of hæmatoidine upon them, but these may be seen in abundance upon the vessel. Gold and palladium staining color the growths slightly; osmic acid also colors them, but not as deeply as it does the surrounding tissue. This microscopic mass is to be distinguished from amyloid degeneration, and from the deposits found in syphilitic cases. The fact that these bodies have been found in the vicinity of capillaries, or in the course of obliterated vessels, has led me to infer that they are

dependent upon lesions of the circulatory apparatus. I have not observed them near the larger cerebral vessels. They are not aneurismal, and do not appear to have any direct connection with the vascular system.

Miliary hemorrhages are found frequently in cases in which aneurisms do not exist, the amount of blood extravasated depending upon the size of the vessel. Miliary hemorrhages vary in size from one-eighth to one-thirtieth of an inch, or even smaller. The hemorrhage is usually limited, but occasionally it involves large areas and produces characteristic symptoms. One point in connection with hemorrhage, not due to the rupture of aneurismal sacs, I have not seen noticed by any writer, and that is the tendency to extravasation of blood into the gray matter. This form of bleeding I have usually found confined to the posterior convolutions. A section through a convolution thus involved, shows that all the vessels are more or less diseased, and that the hemorrhage has taken place from all of the vessels in the vicinity, and apparently at about the same time; the smaller capillaries show small clots, which may at first be mistaken for aneurisms, but careful inspection will reveal the difference.

In these cases it is quite difficult to determine just where the capillary is ruptured, the closest scrutiny with the highest powers of the microscope sometimes failing to disclose the opening. It may be that the degenerated vessels permit a passive hemorrhage, the blood slowly transuding through the softened walls. This form of bleeding is not infrequent; I have found it in all forms of insanity consequent upon engorgement, but especially in those cases of dementia which some writers have denominated "acute." The hemorrhage is not always confined exclusively to the cortical substance of the brain, but is much more frequently found there than elsewhere, and is more extensive than in the white matter. The results are the same as in other forms of hemorrhage; absorption slowly occurs, and cysts are formed, or local softening takes place. Nearly always the remains of a vessel may be found in or near the cyst. In the convolutions of the brain of the infant, already alluded to, numerous cysts were found, in some of which the vessels were apparently intact, but enveloped with granular *débris*. The microscopic appearances of the circulatory apparatus indicate that in a certain proportion of cases the initiatory processes of disease have their origin in the capillaries or arterioles.

Nerve-fibres.—The nerve-fibres undergo changes which must seriously interfere with their normal functions, independently of the diseased tissues around them. The most common changes are hypertrophy and atrophy. Hypertrophy, though not frequent, is found in certain cases, and appears to depend upon increased growth of all the parts of the fibre. The tubular membrane, or sheath of Schwann, grows more rapidly than the other tissues, and is proportionately thicker than in its normal state. The fibres must be examined as soon after death as possible, and should not be placed in any fluid, as the outlines change rapidly after being immersed. In hypertrophied fibres, the tubular membrane sometimes appears to be formed of several delicate layers of tissue, presenting a wavy appearance. The myeline is increased in quantity, and is granular. The axis-cylinder contrasts strongly with the dark tubular membrane, and presents a molecular appearance.

The most remarkable hypertrophy of nerve-fibres that I have ever seen, was found in the cerebral tissue of a person aged forty-seven, who had been maniacal for a year. The brain tissues, generally, were diseased, the vascular system presenting the enlarged appearances already de-

scribed, and the coats of the capillaries having in many places undergone fatty changes. Twenty measurements of nerve-fibres were made soon after the patient's death, giving results as follows: one field contained a number of fibres $\frac{1}{200}$ of an inch in diameter; several fields showed fibres of an average diameter of $\frac{1}{250}$ of an inch; others again of $\frac{1}{330}$ of an inch; while in one instance the entire field was covered with fibres ranging from $\frac{1}{166}$ to $\frac{1}{530}$ of an inch. The largest fibres were found arranged in parallel bands. The same group of fibres, measured at different places, gave the same general results, the fibres ranging from $\frac{1}{530}$ to $\frac{1}{166}$ of an inch in diameter. The portions measured were taken from different parts of the brain, and there was no great difference observed in the several fields as to size. Atrophy of the nerve-fibres from pressure of adjacent growths, or from prolonged capillary engorgement, is of common occurrence in cases of chronic insanity, particularly in elderly people; so considerable is this atrophy, at times, that it is difficult to distinguish the tubular membrane, nothing but the axis-cylinder being clearly marked.

Changes in the Neuroglia.—Since Virchow first demonstrated the neuroglia, several forms of disease have been described which are attributed to morbid changes of this tissue. The most common form of change has been called sclerosis, to which name several affixes have been given; thus there are disseminated sclerosis, multiple cerebral sclerosis, and insular sclerosis. The varieties above enumerated can be seen without the aid of a lens, and they are believed to depend upon an increased growth of the neuroglia. This hyperplasia of the connective tissue, as it is sometimes called, plays an important part in several forms of nervous disease not necessarily involving the mental status of the individual affected.

Certain changes in the appearance of the cerebral tissues, which have recently been brought to the attention of neuro-pathologists, have been described under the name of Miliary Sclerosis. In this form of disease, it is usual to find, scattered about the field of the microscope, a number of white spots, situated in the white matter of the convolution. These spots are not stained by carmine, and contrast sharply with the surrounding tinted tissue; they vary in size from $\frac{1}{200}$ to $\frac{1}{35}$ of an inch in diameter; they are generally round, with well-defined margins; and the adjacent tissue has the appearance of having been pushed back, as though the new growth had formed rapidly. These spots are granular in appearance, and on some, connective-tissue fibres can be seen. They are found in the white matter of the convolutions, in the corpora striata, the optic thalami, the medulla oblongata, and the spinal cord; some are found between the gray and the white matter, and some in the gray matter itself. The nerve-fibres appear to bend around the spots in some places, or they may terminate in them. This is particularly noticeable in the medulla oblongata, where it is common to find the nerve-fibres either bending around, or frayed out in, the spots. Occasionally one of the spots forms about a capillary, which it destroys, in and beyond the mass. Some of the spots are ovoid in form, and, when so shaped, the long diameter corresponds to the axis of the nerve-fibres; again they are sometimes found lobulated, the lobes generally being of unequal size, but apparently developed from a central point; some of the spots have a delicate greenish tinge, and this tint is the same whether the tissue has been previously hardened in spirits, or in other agents.

These spots have been found in the fresh tissue; in one case, an entire

section of the medulla, made soon after death, showed the tissue studded with them; and subsequent sections made from the medulla, after it had been hardened, showed the same general appearance as in the fresh state. The spots are best studied, however, in hardened tissue that has been stained with carmine or with chloride of gold; when the latter substance is used, the spots are slightly colored, but not uniformly stained to the centre, except in the smallest masses; chloride of palladium colors them brown, and a solution of osmic acid turns them dark brown or black. When placed in a solution of osmic acid, they can be seen to change color immediately, before the adjacent nerve-tissue changes; three or four minutes' immersion in a one per-cent. solution suffices to render them black, and when thus stained the spots appear more granular than when stained with other agents.

There are several varieties of this form of degeneration, each one presenting distinct characteristics; sometimes the spots are decidedly fibrous in appearance, the fine stroma of delicate fibres being distinctly visible when examined with a one-tenth objective. In other cases they are amorphous, or but slightly granular, and with no apparent nucleus. The margins of some of the smaller granular spots are clear and distinct, while the margins of the larger spots in the same section may be irregular and apparently interlaced with the surrounding tissue. In the fibrous masses, the fibres do not run in one direction, but interlace with each other at all angles. The fibrous spots occur sometimes in tracts affected with gray degeneration, which would seem to indicate that the two forms of disease are separate and distinct. In one well-marked case of gray degeneration, affecting the medulla, pons, and cord, in an epileptic, the degenerated masses were found in several sections to be situated directly in the tissues affected by the gray degeneration. It was observed that where sclerosis did exist, the spot was distinctly fibrous; where sclerosis did not exist, the spot was not fibrous, but presented the slightly granular aspect already described. In the case alluded to there were large patches, $\frac{1}{20}$ inch in diameter, in the sclerous portion, while in the tissue not affected by gray degeneration there were granular masses $\frac{1}{1000}$ inch in diameter; some of these smaller patches were lobulated, and had well-defined edges. As above stated, none of the masses had nuclei, and no characteristic granular spot could be discovered which could be regarded as a nucleus; nor could any of the detritus of broken-down nerve-tissue be found in the masses, excepting where sclerosis or gray degeneration had previously existed. No trace of resemblance could be observed between the diseased spots and the normal tissue, even in the most recent cases, and before chemical agents had been employed to prepare the tissue for preservation.

Another form of disease, found quite frequently in certain cases, has been called Colloid Degeneration; the name does not appear satisfactory, for, except in color, the diseased parts do not resemble colloid growths, nor do they respond to the reagents which are known to affect colloid tissue. The so-called "colloid growths" of the brain are much smaller than the masses above described, ranging from $\frac{1}{500}$ to $\frac{1}{4000}$ of an inch in diameter; they are more numerous than the patches of miliary sclerosis, have well-defined margins, and are more even in appearance and smoother than the miliary spots. They occur altogether in the white matter, which in certain places is filled with them.

In cases of insanity complicated with syphilis, growths of another form have been noticed; these are as large as the miliary spots, but

not as distinct, the margins shading off into the surrounding tissue. They are more decidedly granular, or rather cellular, in structure, the cells having nuclei, and there being a fibrillar stroma. Still another form of growth has a distinct margin, but the mass appears to be surrounded by a dense membrane, arranged in layers, the interior of the spot appearing smooth and slightly molecular, but without a nucleus.

Five distinct forms of growth have been recognized, and subjected to such tests as experience has dictated, each presenting peculiar and distinct reactions with the agents employed, and each having an affinity for certain special staining materials; though osmic acid, in varying degrees of intensity, stained all the sections subjected to it, with such differences, however, as to leave little doubt that they were unlike each other in structure. It should be stated that these tissues were subjected to tests for cerebrin and lecithin, and to the most delicate tests for albuminates; and that the substance which the larger spots (miliary sclerosis) most resembled, and of which the test gave the most decided, characteristic reaction, was cerebrin; but that the reactions noted at the time were not sufficiently certain to warrant the assumption that this material entered largely into their composition. The smaller masses did not give the same reaction, and we are left without certain knowledge as to their true structure. It should also be stated that comparative examinations have been made of the central nerve-structure of the lower animals, as well as of the central nerve-tissue of persons who died sane, and who were suddenly deprived of life by accident. In nearly every instance, the tissues were placed, part in alcohol and part in chromic acid, or other hardening agent, but the results were substantially the same as far as the diseased portions were concerned.

The masses of degeneration are found most frequently in the anterior portions of the cerebrum, in the white matter of the convolutions; next in the medulla, pons, and cord; and less frequently in the cerebellum. In some cases, they are most numerous in the upper part of the medulla, and it has been observed that while they are sometimes very numerous about the region of the olivary bodies, there are comparatively few in the olivary bodies themselves. These masses are frequently found in the lateral columns of the cord, sometimes encroaching upon and almost obliterating the central canal, for a considerable distance; and in these cases the epithelium lining the canal is altered in structure, and oftentimes its outline cannot be seen. In attempting to follow the course of nerve-roots, these spots are sometimes found encroaching upon them, fraying out the fibres, and destroying the continuity of the root itself. In cases in which the roots of the nerves of special sense are seriously interfered with, hallucinations referable to the nerves affected are observed among the symptoms during life.

Nerve-cells of the Cortex.—The nerve-cells are subject to changes in structure and form, being in some cases hypertrophied, in others atrophied, and in others again in some stage of granular degeneration, or of pigmentation. Changes in the nerve-cells are quite constant. There is not a particular change for each form of mental disturbance, nor do I regard this as important, but the change in the structure of the cells is to my mind of the highest significance. While it has not been shown that the nerve-cells are directly concerned in mental processes, yet the majority of writers consider that intellectual vigor is dependent upon the normal state of the nerve-cells, and that these are immediately concerned in all our mental operations; and when it is found, in a large

number of cases, that degeneration of the nerve-cells is concomitant with impairment of intellect, it is fair to assume that mental integrity depends upon their being in a normal state. Granular changes in the cells are the most frequent in all forms of insanity, the degree of disorganization appearing to depend to some extent upon the violence of the disease; the most complete metamorphosis of cell-structure is sometimes found in acute cases which have run a rapid course. This form of degeneration has been denominated fatty, but the cells do not always show the reactions incident to this condition; the chemistry of the subject is, however, as yet crude, and the tests employed cannot be relied upon when such delicate tissues as nerve-cells are involved.

In the initial stage of granular degeneration, a few yellowish specks appear scattered about in the substance of the cell, at first not affecting the nucleus. These specks increase in number as the change progresses, until the entire body of the cell, including the nucleus, becomes involved, and the cell-wall partakes of the same change; ultimately the cell loses its contour, and is converted into a mass of granules, the polar prolongations having previously become atrophied and indistinct. In atrophy, the whole cell appears shrivelled, and its investing membrane is shrunken. The poles become considerably shorter, and appear to lose some of their substance, and the whole cell and its appendages seem to be surrounded by a clear space. This atrophic change sometimes continues until the cells lose their characteristic appearance, and the poles disappear. The large pyramidal cells are sometimes found in a condition of hypertrophy, but it is not a frequent occurrence, nor is it usual to find hypertrophied cells in all the convolutions; they appear most frequently in the parietal convolutions, and seem to depend upon some local cause. The atrophic and granular changes are nearly always general, as far as the pyramidal cells are concerned. These large cells are often seriously affected, while the smaller cells do not present the same form of change in so distinct a manner. In cases of dementia of long standing, the large pyramidal cells are affected by the granular change, more generally, I think, than in any other distinct type of mental disease. In general paresis, the large cells are also granular, but are less shrivelled, and contain pigment granules. When the nutrition of the brain-tissue has been interfered with by thrombi plugging the capillaries, the nerve-cells in the parts deprived of blood have been found atrophied and granular, and in these cases the lesion is localized, appearing only in those parts of the convolutions which are deprived of nutriment. That the same form of degeneration may be found in mania and melancholia, for instance, does not militate against the inference that both forms of alienation may arise from the same cause, the external expressions of the disease depending upon some other circumstances. Whatever may be the function of the cells, it cannot be properly performed when they are affected by a destructive process which transforms a part or all of their substance into a material so wholly unlike the normal structure that the characteristic features of the cell are entirely lost, and its attachments to the surrounding nerve-fibres severed.

That part of our subject which relates to the pathological states which are characteristic of certain forms of insanity, must be approached with caution, as it is yet a comparatively new field; but it is the practical result which is expected to follow from a study of the morbid conditions of the brain, and it must eventually play an important part in deter-

mining the therapeutics of mental diseases. To illustrate this subject, I have selected typical cases from the well-pronounced forms of insanity, and will briefly describe the pathological conditions found in each.

Acute Mania.—In one case of acute mania, death having taken place on the tenth day after the earliest manifestations of insanity, the capillaries were found in the first stage of fatty degeneration; the granules were situated along the inner walls of the vessels, and also between the vessels and their sheaths; and many of the capillaries which were undergoing this change were found plugged by minute thrombi. The perivascular canals were not seriously dilated, and the adjacent brain-tissue had not undergone atrophic change. The nerve-fibres were not impaired; small spots of degeneration were seen, but they were few in number, not more than six or eight being seen in a section; they were $\frac{1}{3000}$ of an inch in diameter, and were molecular, but with no nuclei; the margins were distinct. Sections stained with carmine presented the same general appearance; the perivascular sheaths were more distinct, and the contrast between the patches of degeneration and the nerve-tissue was greater; the patches were slightly tinged with the coloring matter. The pyramidal cells were clearly defined, and larger than in the normal state; in these enlarged cells fine molecular material was found in the plasma. In the parts of the convolution which had been deprived of blood by thrombi, the cells were more seriously impaired, the molecular matter in the body of the cells being more abundant, and some of the cells being atrophied.

In a case of puerperal mania, in which death occurred six weeks from the first manifestation of the disease, the pyramidal cells were found slightly enlarged, and molecular material was deposited in the plasma. The cells were not well stained, apparently repelling the coloring fluid, and the outlines were a little indistinct. The capillaries were undergoing the first stage of fatty change, and many were found plugged; there was also slight engorgement. The white matter was studded with spots of degeneration, ranging from $\frac{1}{4000}$ to $\frac{1}{3000}$ of an inch in diameter; these spots had no nuclei, and were not stained by the carmine.

In a third case, in which the acute symptoms were prominent for six months before death, the changes were much more evident. The pyramidal nerve-cells were decidedly granular and atrophied, the walls appearing shrivelled, and the poles having undergone atrophic change; the masses of degeneration were larger, ranging from $\frac{1}{1500}$ to $\frac{1}{500}$ of an inch in diameter; they were characterized by a distinct margin, and were round, while their structure was molecular. Their cut surface appeared concave; they were not stained by carmine, and presented a yellow tinge. Some large masses were found in the cortex; these were $\frac{1}{65}$ of an inch in diameter, and were lobulated, and without nuclei; they were unstained, and were found near capillaries.

Melancholia.—In typical cases of melancholia of short duration, the lesions observed in the early stages were the appearance of fatty granules in the walls of the vessels, with slight hypertrophy of the muscular coats, and some irregularity in the course of the affected vessels. The perivascular sheaths were slightly distended, sufficiently so to show a departure from the normal state, and to indicate that at some period the vessels had been engorged. The masses of degeneration were confined to the white matter, and ranged from $\frac{1}{4000}$ to $\frac{1}{2000}$ of an inch in diameter; they were molecular and without nuclei. The pyramidal cells were cloudy, slightly granular, but with distinct nuclei; the polar prolongations were unchanged. A notable feature was that the cells were

surrounded by clear spaces, although the bodies of the cells were not apparently atrophied. These spaces were more distinctly marked in recent, than in prolonged, cases of melancholia, in which latter the capillaries were found engorged, tortuous, and unsymmetrical. The canals and sheaths were well shown, the former being much enlarged. Crystals of hæmatoidine were found in quantities about the bifurcations, and in many cases there were miliary hemorrhages. The neuroglia was proliferating, the extremely fine fibres appearing coarse, so that its ramifications could be easily followed. The pyramidal cells were distinctly granular, and some were much hypertrophied. The small spots of degeneration were found in large numbers, unstained by carmine, and without nuclei.

Chronic Mania.—The microscopic appearances of brain-tissue varied somewhat in these cases, but certain changes were quite constant. The evidences of engorgement were marked, the coats of the vessels being extensively hypertrophied, and the remains of vessels being outlined in parts of the tissue. The perivascular canals were large, often dilated to six or eight times the calibre of the vessels. The sheaths were fibrous, and large quantities of minute crystalline material were found deposited upon them, this being noted even upon some of the finer capillaries. Crystals of hæmatoidine were also found in greater abundance than in some acute forms of disease. The large pyramidal cells were extensively degenerated, the shrunken atrophied cells, and the granular masses into which the cells are sometimes changed, being quite common; the nuclei were less distinctly seen than in other forms of disease, and the polar prolongations were impaired. It was in cases of prolonged insanity that the hypertrophied nerve-fibres were found, although these were not common, atrophied nerve-fibres being more frequently met with. The masses of degeneration were large, often $\frac{1}{25}$ of an inch in diameter, and could easily be detected without a lens, in carmine-stained sections.

Dementia.—In cases of long standing dementia, intense engorgement of the cerebral vessels was a prominent feature. Fusiform enlargements, miliary aneurisms, and miliary hemorrhages, were all frequently observed in this form of disease. The nerve-tissue adjacent to the vessels was stained with the coloring matter of the blood, and numerous small cysts, indicative of old miliary hemorrhages, were found in the gray matter. In a case of dementia of long standing, miliary hemorrhages were abundant in the gray matter of the parietal convolutions, and the cysts of former hemorrhages were numerous. The nerve-cells were granular, and sometimes enlarged; the nuclei and nucleoli indistinct; and granular masses often occupied the positions of the nerve-cells. In these cases, the granular cells appeared to have undergone disintegration, the molecules spreading over a considerable space, and free oil-globules being found near.

General Paresis.—The cases of general paresis presented some features in common with those of dementia. The lesions in the membranes have already been described; well-marked cases had extensive fatty degeneration of the capillary walls, and tortuosity of the vessels; crystals of hæmatoidine were found in great abundance, and the minute crystalline granules encrusted the walls of the vessels and the perivascular sheaths. The nerve-cells were shrunken and granular; the nuclei indistinct, or completely obscured; and the polar prolongations not to be seen. There was a marked increase of connective-tissue elements. In the cortical substance, in several cases, a number of stellate, crystalline bodies were

found; these varied from $\frac{1}{6000}$ to $\frac{1}{5000}$ of an inch in diameter, and had distinct, black nuclei. The masses of degeneration were lobulated, and were not as numerous as in other forms of insanity; they were usually attached to the walls of vessels, which were shrunken, and were often found close to the gray matter. The nerve-fibres were atrophied, and the appearance of the tissue was indicative of active degenerative processes. In the spinal cord there were frequent departures from the normal state, involving the membranes, which were in many cases affected like the membranes of the brain; the nerve-fibres of the posterior columns of the cord were atrophied in the advanced stages, and there was an increased growth of connective tissue.

Insanity of Epilepsy.—In insanity following epilepsy, the nerve cells were found pigmented to some extent, particularly in the medulla and upper part of the spinal cord. The cells of the posterior convolutions of the brain were similarly affected, the bodies of the cells being pigmented and atrophied, while the prolongations were not so seriously affected. Small cysts were found in some cases, and masses of degeneration appeared in the medulla in great numbers, the masses being of the largest size, cellular in structure, and with a fine fibrillar matrix. Changes in the nerve-fibres of the spinal cord were not infrequent; gray degeneration in its various stages was quite common, and longitudinal sections showed atrophied nerve-fibres, and increased growth of connective tissue.

There are, of course, broad divergences from the above described conditions, the great range of diversity being in the various states of the neuroglia and the masses of degeneration. We know very little about the physiology of cerebral connective-tissue, and still less of the influences which affect its integrity. The spots may all be due to an abnormal state of this tissue, but up to this time I have not been able to demonstrate this point satisfactorily. It does not seem probable that the various changes can be due to different stages of the same disease. In the cerebral tissue in one case, there was gray degeneration of the columns of Turck; and in this degenerated tissue, patches of so-called miliary sclerosis were found, and, at its side, the smaller masses which have been described under the name of colloid degeneration. In the patches of gray degeneration, connective-tissue fibres were abundant; in the masses of sclerosis situated in the degenerated columns, the spots were composed of cells imbedded in a fibrous matrix; and in the adjoining tissue were found the small spots with distinct margins and molecular structure. The patches of gray degeneration were deeply stained with gold, the masses of sclerosis much less so, and the molecular spots not at all. In unstained sections, the differences were as marked as in those which were stained. The polariscope and tourmalines gave evidence that the formations were not all of the same structure, and aided materially in determining the differences of the several forms of disease; none of the spots, when under the polariscope, gave the black cross and ring of amyloid bodies.

From a study of these varying conditions, the conviction has forced itself upon me that the degenerations are not always the result of proliferation of the neuroglia, but that in some instances they follow slow inflammatory processes, resulting in degeneration of portions of the nerve-tissue, and causing atrophy of nerve-fibre by direct pressure. It is noteworthy that in all cases in which well-formed spots of degeneration were found, of whatever type, there was an inflammatory condition of the meninges, and an exudation of serous fluid into the sub-arachnoid space, and into the lateral ventricles.

These observations are based upon an examination of one hundred and fifteen cases, embodying all common forms of mental alienation; and while they do not cover the entire ground, the principle microscopic lesions observed have been given. It need hardly be said that one of the results of this investigation, has been to place me among the ranks of those who believe in the somatic origin of insanity; and, further, I believe that the only successful method of arriving at a definite knowledge of the pathology of insanity, is to be found in a study of the pathological histology of the cerebral tissues. We must appeal to the microscope for an explanation of those mysterious phenomena which, under the name of insanity, have so long baffled the Philosopher, Theologian, and Physician. The mysteries will yield to the careful student of Microscopic Pathology.

[Thirty-six photo-micrographs, illustrating the various pathological alterations of brain-tissue described in the paper, were then exhibited by means of the lantern.]

Discussion on Dr. Kempster's Paper.

After the reading of the preceding paper, Dr. Isaac Ray, of Philadelphia, said:—I cannot see a paper of so much importance pass entirely without note or comment. Dr. Kempster deserves great commendation for his labors on the microscopic anatomy of the brain, and there can be no doubt that in this direction is the way to successful inquiry into the pathology of insanity. In the case of two persons dying of mental disease under apparently very similar conditions, we may find in the brain of one every possible lesion, and in that of the other, nothing at all. It is somewhat the fashion to sneer at these microscopic investigations, but however indifferent we may consider the results so far, it can scarcely be denied that it is to them that we are to look for further light on this obscure subject. It is foolish to taunt us with our inability to find a delusion packed away in some congeries of cells, or to see a crazy project stamped at full length on a slice of gray matter, but, certainly, if we learn from the microscope something of the initiatory steps in the morbid process—if we are made sure that in every case there is a dilatation of some cells, or a plugging of some vessels—we have made a substantial advance in our knowledge. Very few of us, I suppose, feel competent to discuss such a paper as this, and all may not be prepared to accept the conclusions of the writer, but, none the less, it ought to receive our most careful study.

The President, Dr. John P. Gray, of Utica, said:—I am glad to hear the remarks of Dr. Ray on the value of the microscope in the study of insanity. In the institution at Utica, where I inaugurated this work in the asylums of this country, though we have been engaged in these investigations for a number of years, I consider that we are only in our infancy in regard to the development of this subject. I do not understand Dr. Kempster to claim that the lesions which he has mentioned are constant and peculiar to, or only found in, certain forms of insanity; and indeed such a claim could not be sustained. Winslow remarked, a long time ago, that insanity was due to a peculiar inflammatory process. A recent article in the British and Foreign Medico-Chirurgical Review, on the other hand, in referring to the investigations at Utica, said that we were no nearer to the discovery of the cause of insanity, or to an explanation of its phenomena, through these researches, than our predecessors were through their methods. And it is maintained by good authority that similar morbid changes are found in other diseases of the brain. What we are endeavoring to do by microscopic investigation, is to determine the exact character and extent of the morbid lesions in insanity, and we think that photographic illustrations and illuminated sections of tissues, such as Dr. Kempster has here thrown upon canvas, are valuable methods of demonstrating these lesions. And all this should tend to stimulate further investigation.

THE RESPONSIBILITY OF THE INSANE FOR THEIR CRIMINAL ACTS.

BY

ISAAC RAY, M.D.,

OF PHILADELPHIA.

How far insanity should be received in excuse for crime, is a question on which, as we all know, there still exists much diversity of opinion. Notwithstanding that the study of metaphysics has, of late years, engaged the attention of some of the profoundest thinkers of the time; notwithstanding that better opportunities for the study of insanity have been afforded by the modern practice of gathering its subjects into large receptacles for care and custody; and notwithstanding that cases for legal adjudication in the courts of justice have been increasing with remarkable rapidity, we are yet, apparently, as far as ever from well-settled conclusions respecting the exculpatory effects of mental disease. Among lawyers and among physicians; among men of science and culture as well as among men who pretend to neither; among men of extreme conservatism as well as among those who are never satisfied with the present—in each and all of these classes, we find, on this subject, most diverse and even opposite views. This we may be inclined to regard as unwarrantable under the circumstances, proceeding as it does from neglect or careless use of the information at our disposal, yet, considering the part which passion, prejudice, and illogical reasoning, have in the formation of all opinions, it is neither strange nor extraordinary.

In the history of English jurisprudence, insanity, as an excuse for crime, scarcely made its appearance until within a comparatively recent period. Towards the middle of the seventeenth century, it may have been recognized as such in some of its grosser forms. With that better understanding of mental phenomena, and that milder treatment of human infirmity, which began to be visible in the literature and science of a somewhat later period, insanity became an unquestionable element both of moral and of legal irresponsibility. Lord Hale undertook to define, with some show of precision, the exact extent of its influence upon the mental movements, and consequently of its effect in impairing the responsibility of its subjects. In this attempt he was guided, unquestionably, by the best medical opinions of his time, as he found them in books, and in the discourse of eminent members of the medical profession. As the result of his inquiries, he came to the conclusion that insanity in its milder forms was not necessarily incompatible with responsibility for crime, while he freely admitted that in its severest manifestations it was an ample excuse for any criminal acts that might be committed under its influence. And ever since, his successors on the English bench have been seeking for some tests whereby these two grades of the disease might be distinguished, the one from the other, but always with very indifferent success; although, moved by that spirit of humanity which has been steadily infusing itself into the English law, their instructions in par-

ticular cases have become more and more frequently correct. The tests which have been promulgated from time to time, not being founded on any correct knowledge of insanity, have each and all proved unsatisfactory when scrutinized under the light of practical observation; but, notwithstanding, they are still put forth occasionally as the law of the land. The discredit into which they have fallen, has somewhat, but not in a corresponding degree, widened the application of the plea of insanity in criminal cases, while it seems also to have given rise to some extent to the very opposite condition, the now prevalent distrust of the plea being supported by reasons which, though far from being new, have recently become endowed with a significance quite unwarranted by what we know of mental operations under the influence of disease. They are no less satisfactory, however, to that large class of people who having taken their opinions from one another, with but little knowledge of the subject itself, find it convenient to allege some plausible grounds for their belief.

In the light derived from a good deal of intimate intercourse with the insane, and from the study of various authors who have written on the subject, I propose to examine the reasons now most often given for withdrawing that exemption from punishment which, in a greater or less degree, the insane have hitherto experienced. I am not so sanguine as to suppose that any efforts of this kind will turn the current of opinion now setting against these unfortunate victims of disease, but the solitary inquirer, sincerely seeking for the truth, should not be obliged to seek in vain.

Much, if not most, of the present feeling on this subject may be traced to the legal profession, by which the plea of insanity has never been very cordially received. To lawyers, it seems like an intrusive element having no proper place in our legal system, but which, nevertheless, cannot be kept out of it. It implies, as we all know, a scientific fact to be examined, and its significance determined, by the rules and in the spirit of modern scientific investigation. This is a task completely outside of the domain of law. The lawyer has had no scientific training, and his knowledge of physical, and especially of medical, science, is only that which floats on the surface of the current thought. The more that is learned about insanity, the more difficult does he find it, for lack of such training, to determine its exact relations to crime. Even when told that the insane, generally, know right from wrong, what is lawful and what is unlawful, and recognize the distinction between vice and virtue, he is still unable to see what element of crime is wanting in their criminal acts. He looks at them, not from the scientific, but from the legal, or, more properly speaking, the metaphysical, point of view.

When a person commits a criminal act, knowing that crime is wrong and forbidden by the laws of God and man, incited to it, perhaps, by a rational motive—to gratify some passion, or to avenge some injury—evincing design and contrivance in the execution of it, the lawyer is constrained to believe, as a strictly logical sequence, that such a person should be punished. In such an act, not a single ingredient of crime, as he has studied his books, is wanting. A person, he says, who imagines that another, sitting opposite to him at table, is making faces at him, is led to this belief by some morbid condition of the perceptive organs, for which he is not to blame, certainly, but which furnishes no excuse for shooting his imaginary foe, because he knows as well as he ever did that killing or maiming another is wrong and unlawful. Besides, he acted deliberately, he had malice in his heart, and, as the old indictments used

to have it, he was moved by the evil instigation of the devil. What then was wanting to render him responsible? Nothing, certainly, if we leave out of the account those springs of action, no less real and potent, which are introduced into the mental mechanism by disease, and ignore entirely some faculties of the mind, as necessary for determining and regulating the conduct as those which are recognized. He can find no excuse in his philosophy for one who slays the dearest objects of his affection, while admitting the wrong and deploring the necessity which obliges him to do it, simply because he has but a faint apprehension of the mental faculties chiefly concerned in the act, and scarcely any apprehension at all of how they are affected by disease. In short, of the two classes of faculties or manifestations that make up the mind, one, considered as the subject of disease, is altogether ignored, while the operation of the other under stress of disease is greatly misunderstood.

And thus it is that in their theories respecting the responsibility of the insane, the lawyers, in their imperfect understanding of the nature and operations of the mind, commit two serious mistakes; one is that, where the mental affection is too obvious to be overlooked, they measure and define the scope of its influence in an arbitrary manner, unsupported entirely by the facts of psychological science; while the other, as just intimated, consists in regarding the affectional faculties—the sentiments, emotions, and passions—as without any part in the play of disease, or with so little that it may be safely ignored. The first mistake may be witnessed in the rule propounded many years ago by Hoffbauer, a German jurist of great repute, that an insane person may be excused for any act prompted by a delusion, only as far as the act would have been excusable had the belief been a reality instead of a delusion. That is to say, if an insane person imagined that another was approaching him with intent to take his life, he might kill him, and be excused on the plea of insanity; but if he only imagined that this person was making faces at him, or had been following him from one place to another, he should not be so excused, because had the offence been real instead of imaginary, it would not have justified the killing. Never has there occurred a more remarkable instance of this mistake than that presented by the English law-lords, in 1843, on the occasion of the trial of McNaughton, for killing the secretary of Sir Robert Peel. McNaughton was possessed by the delusion that he was pursued by enemies who, though unknown and unseen, completely destroyed his peace. In fact, he was laboring under what is now called the *mania of persecution*. He had somehow connected Sir Robert Peel with this conspiracy, and concluded to shoot him; but mistook his secretary for him, and killed the latter instead of the prime minister. He was acquitted on the ground of insanity, but the public rebelled so strongly against the verdict that the matter was brought before Parliament, which instructed the law-judges, twelve in number, to confer together and decide what the rule should be in cases of this kind. They agreed upon the rule put forth by Hoffbauer, as above described, and accordingly it was announced authoritatively as the law of the land.

We may well be astonished that a rule which is to decide the question of life or death for all coming time, should evince the grossest ignorance of the mental operations when affected by disease, and should be put forth, too, by a body of men who might be supposed to be more correctly informed. The rule, be it observed, implies mental disorder, and consequent irresponsibility, the extent of which, however, is limited in an

arbitrary manner, with no reference at all to the pathological condition. It means that if a person imagine that enemies are waylaying him at every turn, he may not be accountable for that belief, because it has intruded itself into his mind without any will of his own; but that, it being there, he is accountable, to some extent at least, for what he thinks and does about it. He is required to act respecting it very much as if he were perfectly sane—killing his fancied enemy if he apprehends from him a murderous assault, as a matter of self-defence, but resorting to the courts for redress, if his enemy has only assailed his reputation, or is preventing him from obtaining certain estates. That there is any ground for such limitation, no one can admit who has been much conversant with the insane. Indeed, the fallacy of the principle in question is obvious enough without any experience of this kind. Everybody knows that the man who imagines that his legs have turned to glass, goes about as usual, instead of keeping still and thus making his conduct consistent with his belief.

How a principle so plainly and completely contradicted by the facts of science, should have obtained the currency that it has, is not easily explained. In England, this, as well as some other mistakes on this subject, may, possibly, be attributed to a famous dictum of Locke, who said that madmen reasoned correctly from false premises. Locke knew as little about insanity as the English law-judges, otherwise he would have known —what the humblest servant in a hospital for the insane knows—that the insane may wander at every step of their reasoning, from premises to conclusion. It is no more than might have been expected, that one who insanely believes that his neighbor has been telling bad stories about him, should also believe himself justified in taking that neighbor's life. The confusion of ideas, so flagrant and so common in discussions upon this subject, is well illustrated by the fact that the judge who presided at the trial of McNaughton, and who approved of his acquittal, subsequently joined the other judges in declaring Hoffbauer's rule to be the law of the land. Under this rule, McNaughton should have been convicted, for, crazy as he was, he certainly apprehended no personal harm from Sir Robert Peel. Another instance of this confusion of thought was exhibited by one from whose multifarious knowledge and keen sagacity something better might have been expected. Lord Brougham said in Parliament, on one occasion, that he could conceive of "a person whom Deity might not deem accountable, but who might be perfectly accountable to human laws." In other words, a mental disorder which would render a criminal act excusable in the eyes of God, might be entirely ignored in the judgments of men. In this statement Lord Brougham did not merely mean to declare—what nobody would deny—that man, with his limited apprehension, might fail to discern mental disturbances that would be perfectly obvious to the eye of Omniscience; he meant to assert the doctrine that a kind and degree of mental disorder, equally obvious to God and man, might lead one to excuse, and the other to punish, any criminal act that might be committed under its influence. How such a monstrous conclusion could be reached, except in defiance of all reason and religion, is not very obvious. We can account for it only on the supposition that, to the mind of the thorough-bred lawyer, it seemed imperative that the legal theory of guilt and responsibility should be upheld at all hazards. For certainly the act in question had in it all the elements of crime, and, of course, the doer of it must be punished, even though God undoubtedly were ready and willing to excuse him.

The other mistake pervading the theory of the law respecting the responsibility of the insane, is to leave out of the account altogether the moral faculties of our nature—the sentiments, passions, and emotions. Here again is another of those inconsistencies which abound in the current reasonings on this subject. While every one admits that in these faculties are the great springs of human conduct, that they incite men to good or to evil, and furnish the motives and impulses by which they are governed, the idea that they, or rather the cerebral organism with which they are connected, may become diseased as well as the reflective faculties, is regarded as preposterous and of dangerous tendency. And yet we have the same proof of the one fact that we have of the other. The conditions of health and disease are precisely the same in both. Both are manifested by the same material organ, the brain, by far the larger portion of which, according to the most prevalent opinion, is given to the moral powers. Disease in any part of the brain must necessarily be followed by derangement of its appropriate function, so that it is in the order of nature that when a certain part of the brain is diseased, there will be some disorder of the affectional faculties. How this conclusion can be denied by any one who believes that disease of the brain may produce loss of memory, of judgment, of attention, and of mental application, is not very obvious. The only possible explanation of this curious inconsistency is that disease of the moral faculties so often resembles manifestations of moral depravity, that it has been mistaken for the latter, especially by those who are not accustomed to regard this subject from a physiological point of view—their notions, as far as they imply any exercise of thought, being founded solely on metaphysical considerations.

And here we see the influence of that school of mental philosophy in which our predecessors were trained. We may safely say, I think, that had Herbert Spencer, and Bain, and Morell, lived and written in the days of John Locke, the popular notions respecting insanity would not now be precisely what they are. Under their teaching, the affectional faculties would have held their rightful place in the mental economy, and would have played as necessary a part in its operations as that of the others in completing the grand result implied in a thinking, social, responsible being. Until they are regarded in this way, we need not expect much improvement in the law of insanity. The tests of responsibility will continue to be what they now are—confined exclusively to the action of the reflective powers. The question will continue to be, did he know right from wrong?—did he know that the act was contrary to the laws of God and man?—did he evince forethought and contrivance in executing it?—ignoring the equally important questions, could he see the moral complexion of the act in its true colors?—had he the power, unaffected by disease, to pursue the right and avoid the wrong; to resist the natural impulses to wrong-doing by the superior force of conscience? Responsibility implies the integrity of *all* the mental powers, moral as well as intellectual. If the mental movement is disturbed by the intrusion of a foreign element, it is immaterial at what precise point this element enters. To suppose otherwise, is as absurd as it would be to suppose that a delicate piece of mechanism could be deranged only at a certain point.

As a consequence of this confusion of ideas, there has occurred a lack of uniformity in the practical application of the rules of law, which, considering the momentous issue involved, suggests no very comfortable reflections. The court may be satisfied of the irresponsibility of the

prisoner, while, under a strict construction of the rules, he must be regarded as guilty; or the jury may prefer to found their verdict on the matters of fact disclosed in the evidence, rather than on the rules of law laid down by the court. And such must always be the case as long as the matter of insanity is treated as a question of law rather than as a question of fact, for here is the source of much of the error that has been committed on this subject. It is especially visible in the current doctrine—as current now almost as it was in the time of Lord Hale—in regard to the exculpatory effect of what is called partial insanity. In some forms of disease, the patient does not seem to be entirely bereft of reason. On some subjects he converses with no lack of correctness or propriety; some business he transacts with his customary shrewdness; and many people meet him in the ordinary intercourse of life without suspecting any aberration of mind. It is not questioned that he still is, in some degree, a rational creature. And certainly it is not surprising that the world should be slow to admit such a mental condition as an absolute excuse for crime. If the person have been entirely rational for some purposes, or in some relations, why may not this circle of rationality have embraced the act for which he is tried? This is a fair question, undoubtedly, and is entitled to a respectful answer. What we complain of, is that, instead of being answered in the light of that knowledge of the workings of the insane mind which is derived from long, clinical observation of the disease, the question is supposed, in actual practice, to carry its answer with it. The logic runs thus: the act *may have been* the product of the reason left untouched by disease; therefore it *was*. We insist that the fact should be proved, and we claim in the interest of true science, as well as of humanity, that the burden of proof lies with the side that denies the influence of the alleged disability. The existence of insanity in never so small degree being shown, it is for the other side to show that it had no part nor lot in bringing about the criminal act. Now we do not deny that this is ever possible, but we do say that in most, if not all, cases, we are positively unable to fix the limits of the operation of disease, and to say that the act in question was not the offspring of disease. No man pretends to discern all the springs and turns of thought even in the rudest sane mind, and it certainly is no easier when the subject of observation is thrown out of its ordinary courses by a disturbing force. We know enough, however, on this subject, to be convinced that, very often, thoughts apparently the most remote and disconnected from one another, are found, on further research, to be closely associated, and thus to lead to conduct otherwise most strange and mysterious. He must have been a superficial or careless observer of insanity, who has not often discovered the most violent acts to be the outcome of a wild and tortuous succession of thoughts. To say that we see no logical connection between the mental condition as obviously manifested, and the criminal act, is simply a confession of ignorance, not a display of knowledge.

In contending that in criminal prosecutions, when insanity is pleaded in defence, the burden of proof should fall upon the side that resists it, we are only following the rule most used in civil cases. There, the existence of insanity having been shown, it is incumbent on the party wishing to establish the act in question, to prove that the person had recovered, or that the act was performed quite independently of, and was untainted by, disease. If a will be in dispute, and the testator be shown to have labored under some unquestionable delusion or weakness of mind,

the presumption is that the will is rendered invalid by the mental affection, and it is left for those who would establish it to prove the contrary, and the rule is the same in reference to contracts. It goes further even, for many a contract has been voided which displayed no indication of unsoundness, and which could not be traced to undue influence. There is not the slightest reason for this difference, in the nature of mental disease. Its agency in the occurrence of crime is as far beyond all our resources of detection, as it is in the making of a will or contract. If any difference is to be admitted, it should be the other way, inasmuch as an issue of life or death is a far more serious matter than one of property alone.

There is nothing in the popular conception of insanity so common or with so little foundation in the nature of things, as the idea that the extent of the malign influence exerted by insanity on the mind, can be accurately measured by the external appearance and deportment as viewed by the casual observer. It is supposed that a person who can converse sensibly, behave properly, and transact business, cannot be so insane as to be irresponsible for his criminal acts. In every trial where insanity is pleaded in defence, this idea is generally the main stay of the prosecution. A host of witnesses is summoned, who testify to perfect soundness of mind. One had frequently met the defendant, passed the time of day with him, and talked about the weather; another had employed him in some ordinary trust or duty; another had had some business-transactions with him, selling him, perhaps, some little necessaries of life, or paying him a trifle of debt or interest; another had met him mingling with company at a watering-place, or at some social gathering; and these persons, one and all, declare that they witnessed nothing strange or unnatural in his looks, discourse, or deportment; and those who had business-dealings with him, and especially if they got a good bargain out of him, declare him to have been uncommonly shrewd. This evidence, though entirely negative, is none the less effective with most of those who hear it. Its force is scarcely weakened by the statement, which they may admit in general terms, that insanity often leaves some operations of the mind untouched, and thus escapes the notice of the casual observer. And yet this trait of insanity would seem to be too common to be so disregarded in actual practice, for every hospital report, every newspaper that we take up, bears witness to its frequency.

In the normal condition, nothing, under ordinary circumstances, is dearer to a man than his life. To preserve it is one of the most powerful instincts of his nature, and, if in certain exigencies he willingly part with it, it is for the rational purpose of securing what seems to him a greater good, or of avoiding a present, real, unequivocal evil. And yet a large proportion of suicides are committed by persons urged by no apparent motives, in the possession of every outward circumstance calculated to make life desirable, and giving no indication whatever of mental disturbance. Up to the last moment, they may have transacted business, conversed sensibly with friends, and in all the relations of life conducted themselves with their customary propriety. Yet who will venture to say that, notwithstanding all these apparent indications of good mental health, suicide, committed under the circumstances just mentioned, does not signify a kind and degree of insanity as destructive of moral freedom and responsibility as the most demonstrative forms of the disease? It is also a well known fact that many of those persons who attempt unsuccessfully to commit suicide, while appearing to the casual observer

entirely sane, subsequently have only the most dim and uncertain consciousness of the attempt. Now, there is no reason to doubt that homicide, and perhaps some other criminal acts, may be committed in a similar state of mind—evincing just as much coolness, deliberation, and contrivance, and just as complete an absence of all the demonstrative signs of mental disease. It is not creditable to the intelligence of our time, that the apparent correctness and propriety of the person in the common relations of life, should be regarded as incompatible with the presence of insanity, or, at least, with any such insanity as should exempt him from responsibility.

Unquestionably, during the present century, the tendency of public sentiment, following, no doubt, that of the clinical study of mental diseases, has been to enlarge the exculpatory effects of the latter. Now and then there have been signs of reaction, never stronger, probably, than at this present moment. To men whose opinions are formed by the current prejudices around them, rather than by any careful study of facts, it seems as if the plea of insanity had been making crime a little too easy, and that a wholesome check to this facility would be found in punishing the insane like other criminals. The argument by which this doctrine is generally supported is that many of the insane know right from wrong, that they are governed by motives, and may restrain their passions. The facts implied in the argument, we willingly admit, for nobody denies that many of the actions of many of the insane are rationally considered and rationally performed. Nobody denies that their conduct may be determined by the hope of reward or the fear of harm. One patient strives hard to obtain a privilege or a favor, while another is deterred from an assault upon a fellow-patient by remembering the threshing he got in a former encounter. The same man who believes that he is coming to want, and destroys himself and family to save them from misery, may refrain, if he please, from exposing his person, from soiling his clothes or from assaulting his neighbor. Why then should he not be punished for offences that are not inspired by his disease? To those much conversant with the insane, the reasons against it are obvious and conclusive. The more that one learns of insanity, the more inscrutable are the movements of the mind affected by it, and the less confidence is felt in any attempt to discern exactly their connections, and to say which can be safely attributed to sanity and which to insanity. If this be so, under the daily and hourly observation of a skilful inquirer, what confidence can be placed in any positive conclusions founded on the testimony of those who have seen the accused at remote periods, who know nothing of insanity beyond what is learnt by the casual sight, now and then, of a person reputed to be crazy, and who are unable by lack of culture to convey to others the impressions thus made on their own minds. If any one could tell us—physician or philosopher, court, counsel, or jury—by what means, with the slightest approach to certainty, we might make the distinction between the working of the sane and that of the insane element, we would not object to the proposed rule. At any rate, let the burden of proof rest on the party which alleges that the criminal act was prompted not at all by the presence of disease.

There is another reason for not punishing the insane, which, feeble as it may be to the common mind, is conclusive to the close observer of mental disease. Admitting, as we do, that much of the daily life of the insane shows no trace of disease, we are none the less sure that the presence of disease, however limited it may appear, is generally incom-

patible with the most correct and vigorous exercise of all the faculties of the mind. It impairs the freedom of the will; it blunts the sense of right and wrong, of the good and true; it weakens the power of self-control, and diminishes the normal amount of restraint upon the appetites and passions. No one engaged in the service of a hospital can have failed to observe how fiercely the passions of the patients are excited by little provocations that would scarcely have ruffled their tempers before; how disproportioned to the offence is the measure of their retaliation; how grossly exaggerated are every feeling and impulse awakened by the ordinary experiences of life; how often native propriety of manner and delicacy of sentiment are replaced by a rude demeanor, and by a coarse, reckless disregard of the rights and feelings of others. Even when the criminal act seems most clearly beyond the range of the morbid influence, there is always reason to suspect, if not to positively believe, that it would not have been committed except for this enfeeblement of the power of self-control, or this blunting of the moral perceptions.

Such being the fact, it shows how groundless is the doctrine, somewhat countenanced just now, of a limited responsibility, as applied to the partially insane, according to which they are always to be punished for their criminal acts, though in a less degree than they would be if unquestionably sane. I need only allude to the doctrine, as its unsoundness has been sufficiently shown by the views already expressed. A moment's reflection must convince any one that no device of legislation could make the application of it in practice otherwise than absurd. The idea of a court or jury constructing a scale of insanity according to its severity, and graduating the measure of punishment thereby, is simply ridiculous, and would be rendered still more so by any attempt to apply it to a given case.

Recently, we have seen the revival of a doctrine, never much in vogue, however, that the insane should be punished in order to deter them, by force of example, from breaking the laws. In support of this view, instances are related of insane persons, who, when talking over the criminal acts of others understood to be insane, have said to each other with much self-complacency, that, being insane, they would not be punished. In this belief, they would naturally use no self-control, and would feel free to break every law on the statute-book. Unquestionably the insane know very well that they may not be punished for their offences, as they know a great many other things. They are able to reason correctly on the subject, as they do on many other subjects. The fact is not extraordinary, nor has it recently come to light, and, considered in connection with other facts, it implies no responsibility. The truth is, that very few of the insane believe that they are insane; consequently, immunity from punishment does not present itself to them as an inducement to commit crime, nor to relax in the slightest degree their control over their passions. While they perceive well enough the abstract nature of crime, they cannot see it as applied to any particular act in their own cases. They are outside of the range of such application, and are a law to themselves. Some are urged by a necessity which they cannot resist, even knowing that they do wrong, and knowing the usual consequences. Some are prompted by strange suggestions: the voice of an unearthly presence, a terror that overrides every thought of consequences, or a spur of savage ferocity unmingled with the slightest sense of humanity. These people act without reference to law or gospel, under motives and impulses as remote from their natural dispositions and principles as the

poles are asunder. The fact that persons reputed to be insane had suffered the usual penalty for their crimes, would have no more restraining influence than blows or threats in hushing the cries of a new-born infant. No human law can be more imperative than that higher law within him which impels many an insane man to some act of violence, and no consideration of justice or pity can come in to lighten the stroke provoked by the trivial offence of a neighbor. Indeed, this idea of the insane being deterred from criminal conduct by penal laws, is utterly destitute of foundation, and we challenge its advocates to produce a single instance in point.

In order to make this idea practically efficient as a means of restraint, some steps would be required to give it an authoritative character, for unless the insane were somehow convinced of their responsibility, clearly and fully, of course it could have no restraining power. There would seem to be an insuperable difficulty in the way of making this idea immediately effective. If left to the courts, the most that could be expected would be now and then a decision declaring insanity to be no excuse for criminal acts. And supposing these occasions to become more and more frequent, until the rule should generally prevail, there still would be a considerable period of doubt and uncertainty as to the actual state of the law. The case could be properly met, if at all, only by an act of the legislature, and, in the present state of public sentiment, nothing is less likely to happen than an act making insanity, of whatever kind or degree, no excuse for crime. If, however, the legislature, without going to this extent, should undertake to specify what forms of the disease should or should not have this effect, as it has in some European countries, the result would be a lamentable failure, producing only confusion and distrust. Our notions of the actual limits within which the operation of any form of insanity is confined, are too vague for such a purpose, and the imperfection of our nomenclature would prevent any approach to uniformity of meaning. And thus we stand: The legislature is indisposed to act, and the rules adopted by the courts are irrelevant, inadequate, and conflicting. Nor from this unsatisfactory condition of the law can we expect any relief, until the whole question of insanity shall be regarded as a question of fact, not of law, as at present; and, thus regarded, shall be taken altogether from the court, and, like other matters of fact, be given to the jury, which would be governed by the weight of evidence and the individual convictions of the jurors. This course is virtually taken by juries, even now, and it is held up as a flagrant instance of our scandalous indulgence of crime, that many a verdict of "not guilty, by reason of insanity," is rendered, in spite of the instructions of the court.

I cannot leave the subject without adverting to an argument in favor of punishing the insane like others, on which unusual stress has been laid in some recent trials. It is represented that in our hospitals for the insane, the discipline is maintained by the use of rewards and punishments. This implies that the patients are deterred from wrong-doing by the understanding that it will be followed by punishment, and the inference is drawn that the same motive would operate in the same way outside, as well as inside, of a hospital. If the statement on which this reasoning is founded were strictly true, it should be taken in connection with the other well-known fact, that many of the insane are not deterred from violence or any other wrong by fear of any consequences whatever. Neither threats nor blows, nor death itself, can turn them from their chosen

course. And thus arises the difficulty which has already presented itself in another shape, that of determining to which of these two classes the accused may belong. By what kind of evidence are we to be convinced that the prisoner at the bar would have refrained from committing the offence for which he is on trial, had he believed that he would be punished?

But we are really not reduced to this dilemma. The idea that the inmates of our hospitals are punished for their delinquencies, is false—entirely without foundation in fact. They are deprived of a privilege or of an indulgence, which they have shown themselves unable to use without harm to themselves or others—an inability which may have been as much beyond their control as the usual manifestations of bodily suffering. Such deprivations, as well as rewards for good behavior, are used as a means of trying and strengthening the power of self-control—a power which in the insane is confessedly weak. Its exact degree of weakness or strength, no one much acquainted with them will undertake to measure; and who then can measure it for the purpose of apportioning the proper amount of judicial punishment? So far is it from being true that the patients in our hospitals are punished for any reason whatever, that the attendants are prohibited from returning a blow, or retaliating for insults or injuries, on pain of dismissal; and yet, when provoked by serious assaults, they might often say with truth, "he knew better; he knew he was doing wrong; and a little summary punishment will help to make him do better in the future." But if to punish the insane be good law in a court of justice, why should it not be in a hospital? We would have it distinctly understood that it is not good law in the latter, not because there is never a case in which punishment might prove a powerful help to improvement, but because no insight short of Omniscience can ever know for certain which are such cases. It may be urged, perhaps, that exception should be made of cases in which it is shown by satisfactory evidence that the accused had often been deterred from wrong-doing by the fear of punishment. The statement is quite too vague to serve as the ground of a general rule; and besides, it is open to the objection of showing a negative rather than a positive state of facts. What a man refrains from doing under certain circumstances, is no safe measure of the extent of his self-control under other and very different circumstances.

That there has been, of late years, much practical disregard of the rules of law, on the part of juries, must be admitted; but the course of judicial decisions and verdicts within a very recent period, shows how grievously potent they still are. About two years ago, one Fordham, a patient in an asylum for the insane, murdered an attendant. It appeared in evidence that he was an epileptic, quarrelsome, and often violent; that he had quarrelled with the attendant, and had declared that he would have revenge. He was tried, and convicted of murder. The court, Mr. Justice Denman, charged the jury that the mere fact that the prisoner was laboring under a delusion as to his treatment in the asylum, as no doubt he was, was not sufficient excuse in law. "If a man killed another," said he, "while under a delusion that he himself was about to be killed, and that he was acting in self-defence, he would not be punishable; but if a man did so for some supposed injury to his character or fortune, then he would be responsible." Sentence of death was passed in the usual form, but the punishment was afterwards commuted to penal servitude for life. Some three or four years ago, Mr. Lutwidge, one of the members of the

Board of Lunacy, while passing through a hospital which he was visiting officially, was assaulted by a patient, who inflicted upon him a wound from which he soon died. The patient's insanity was unquestioned, though he had not been supposed to be dangerous. In speaking of the case, in their annual report, the twenty-eighth, the Board say that the man "was quite responsible for his actions." Since this case occurred a man named Blamfield has been tried for murdering a fellow workman. The act was done suddenly, without apparent premeditation or provocation. Blamfield had been a patient in a lunatic asylum, from which he had been discharged, uncured, some months before. The medical superintendent of the hospital testified that, while in his charge, Blamfield had had a fear of punishment for misconduct, and had been governed by this feeling. He, therefore, considered him responsible for his acts. The man was convicted of murder, and sentenced to be hanged; but his punishment was subsequently commuted.

Such are the more prominent difficulties now in the way of making the plea of insanity in criminal cases as effective as it should be. The question may naturally be asked: How can these difficulties be most readily removed, and the law be administered in conformity with the truths of science? It is scarcely within my purpose to speak upon this point, but it may not come amiss to indicate very generally the direction from which reform may come.

Let me say, in the first place, that if courts are to continue to measure the exculpatory effects of insanity by certain arbitrary tests, they are bound to avail themselves, as did Lord Hale, of all the existing medical knowledge on this subject. Instead of repeating, one after another, rules and distinctions, of which the sole claims to respect consist in the fact of their having been uttered before, it is their duty to learn as much as possible of the nature of insanity from the only true source of knowledge—the practical observation of the insane. Legal knowledge is, for the most part, so technical that the decisions of the courts on most matters are received by the public in faith, nothing doubting; but on this subject, the public will have an opinion of its own. The people who would shrink from the presumption of understanding a question of contingent remainders, or of eminent domain, may have little respect for any rule of law touching the responsibility of the insane. Have we not a right to ask the judges to make themselves acquainted with the nature of insanity by all the means within their reach, so that, instead of directing the jury by a servile repetition of something that others have said before them, with no other authority than the fact that it *has been* said, they shall present only the established facts of science, and such considerations as are naturally suggested by them? Let it be remembered that we are dealing with a branch of medical jurisprudence, and, therefore, that the study here recommended belongs as well to the lawyer as to the physician. I do not suppose, indeed, that the soundest instructions would always be followed by a proper verdict, for juries are too fond of manifesting their independence by disregarding whatever may conflict with their own foregone conclusions. But it would remove somewhat the distrust now felt of judicial decisions, in which the advancement of knowledge is entirely ignored, and would prepare the way for a better and more satisfactory administration of justice.

A still better step, as above intimated, would be that already taken by the courts of New Hampshire, whereby the question of responsibility

is treated as a matter of fact, not of law, to be determined, like other matters of fact, by the jury. In the performance of this duty, juries would be governed by the evidence, aided by the explanations of the experts. This would not necessarily insure a correct verdict; for the evidence might be conflicting, the experts might disagree, and the jury might be governed more by its prejudices than by the real merits of the case. It is doubtful, however, if anything better could be obtained under our mode of procedure, and this is not likely to be changed at present. Some improvement might follow from putting into the jury-box men of higher personal character, moral and intellectual, than such as are often found there. This improvement could be more easily made, I am sorry to say, than could one equally if not more efficient, whereby the experts should prepare themselves more carefully for their duty, and should discharge it, divested of every unworthy bias.

Discussion on Dr. Ray's Paper.

After the reading of the preceding paper, Dr. Clement A. Walker, of Boston, said:—I wish to express my sense of obligation to Dr. Ray for the clear and distinct manner in which he has presented this subject in his valuable paper. Just now, such papers are much needed, for there seems to be at present a reaction setting in against the insane, causing them to be held responsible for acts committed while under the influence of insanity. This reaction is particularly strong in Massachusetts, where the action of the executive in commuting the death penalty to imprisonment, in the case of a man convicted of murder, and who was by many regarded as insane, has been received with astonishment, and has been condemned as an unjust act. There are some in our specialty who may differ with the ideas of Dr. Ray in regard to the limited responsibility of the insane, but his views in this respect have my full endorsement.

The President, Dr. John P. Gray, of Utica, said:—I do not agree with Dr. Ray in drawing such a distinct line between the intellectual and moral elements of the mind, for this would divide the mind into parts, and would give, as a logical result, moral and intellectual disorders, independent of each other. I believe in the essential unity of mind, and I cannot assent to his view either as being sound psychology, or as true in clinical observation. I observe, however, that, though Dr. Ray makes this theoretical separation, yet when he comes to treat of actual insanity, and of responsibility, he reunites the moral and intellectual faculties.

THE SIMULATION OF INSANITY BY THE INSANE.

BY

C. H. HUGHES, M.D.,

LATE SUPERINTENDENT AND PHYSICIAN OF THE MISSOURI STATE LUNATIC ASYLUM.

THE literature of insanity feigned by the sane mind is extensive, and dates back to the earliest period of recorded history. The feigning of Ulysses in profane, and of David in sacred, story, are familiar to all, as is likewise the history of Lucius Junius Brutus, who saved his life by successfully assuming imbecility, and Shakspeare's two oft-quoted examples in the characters of Edgar and Hamlet—the latter, I think, blending some actual mental disease with simulation; but upon the subject of the present paper, the simulation of insanity by the insane, not much has been written, though enough is known to make it a proper subject of inquiry.

Not less interesting to the student of morbid psychology than the well-defined, well-recognized forms of insanity, are those obscure, anomalous conditions of mind which occasionally appear, but in regard to which he fails to obtain any light from the standard books. Though more numerous, probably, than they are generally supposed to be, yet they are comparatively so rare, and so imperfectly understood, that, for the most part, after exciting a little temporary curiosity, they pass from attention, and are forgotten. And yet they must ever constitute a very important class of mental disorders, for the reason that their existence, however infrequent, must necessarily modify the conclusions that might be drawn from the more common forms of mental disease. In fact, no physician needs to be told that many important steps in the progress of his science have been made by the careful and persistent observation of what, at first, seemed to be anomalous and exceptional cases.[1]

The meagre record of cases of simulation by the insane, to be found in the literature of psychiatry, may be due partly to the fact that the necessity of searching these cases out, has not been so imperative as the detection of feigning by the actually sane, who so often simulate insanity to defeat the ends of justice, and for other sinister purposes; partly to the fact that proof of simulation, in the case of persons already adjudged to be insane, possesses no real, practical value; but mainly to the fact, which I think observation has established and will continue to prove, that the insane do not, in general, assume either different degrees or forms of insanity from those with which they are actually afflicted.

We might here paraphrase a familiar quotation, and say *in maniâ veritas*, for the lunatic is generally true to the promptings of, and mainly dominated by, his acquired, morbid nature. To the practised eye, a tinge of insanity colors nearly all that a general lunatic says or does, and it is doubtful if, in the acute stage of profound and constant general mania, the actually insane do ever simulate. The general insurrection and rebellion of all the ideational and emotional centres which seem to

[1] Dr. I. Ray, Remarks introductory to case of Bernard Cangly: American Journal of Insanity, July, 1865.

characterize this form of mental alienation, the universal tumult into which all the faculties of the mind are at this time thrown, would seem to leave no room for the planning and contrivance essential to simulation, though it be never so imperfectly done. The assuming of a character different from the dominant and all absorbing morbid impulses of the individual, would be contrary to all observation in acute, general mania, and is to my mind impossible, notwithstanding the existence, in this form of mental disease, of considerable method and shrewdness in planning and executing in the direction of morbid fancies and inclinations. To attempt simulation would only seem possible, if possible at all in this form of mania, after the violence and excitement had passed away and the disturbed faculties had become comparatively calm, with the return of some degree of rational appreciation of acts committed and of penalties incurred, and to be avoided, and with an obliviousness, on the part of the individual, of the fact of his insanity. Here the question would present itself as to the actual existence of insanity at the time of feigning, while its pre-existence might be readily conceded.

Feigning has the nature and quality of rationality, and is rarely, if ever, practised without a motive. It proceeds *primâ facie* from a rational mind, just as motiveless acts proceed *primâ facie* from a mind deranged; yet we know that all acts without motives are not the offspring of insanity, as we know that acts prompted by rational motive do not proceed from the sound mind only. We sometimes see, however, a kind of unconscious imitation, in some exceptional, morbid, mental states, of psychopathic and neuropathic conditions seen in others, and occasionally a kind of simulation lacking the conscious element in real insanity—a mere freak of disease—which, however, is scarcely worthy to be called true simulation. The insane appear at times, when they have an object to accomplish, more crazy than, and different from, what they really are; this is the sense in which we use the term simulation, and this condition is akin to that of feigning by the sane.

Of course we do not expect to find feigning in advanced, general dementia; but we may not search for it in vain in the intervals and remissions of recurrent or periodical mania; after the mania transitoria; possibly in certain stages and forms of what is called chronic, general mania; in the hysterical and partial forms, the so-called monomanias; and in the moral or affectional forms of insanity—the "*manie sans délire*" of Pinel. Let me, however, repeat, to be plain, that in that profound, general involvement of the mind in disordered action, which depends probably upon more or less implication of the whole brain, and which we term acute, general mania, feigning would seem an impossibility. The psychical conditions essential on the one hand to simulation, and on the other to the truthful acting out of acute, general, mental disease, seem incompatible; the real victim of such a malady would not be sane enough to simulate, except during a so-called lucid interval, and comparative or entire freedom from disease.

Simulation, while it presupposes a degree of sanity, does not require that the patient should be wholly sound in mind, and might be attempted by a convalescent patient, not thoroughly recovered, for the purpose of remaining longer in the hospital or for some other reason. Supposed feigning, in what appears to be a case of acute, general mania, should lead us to suspect the correctness of our diagnosis, and to review the steps by which we have reached the conclusion that the person is actually insane. I am not prepared to say this much of other forms of mental

disease, except dementia. We may admit the possibility of subsequent feigning after the subsidence of a paroxysm of acute, general mania, and still hold to its general improbability, simulation being, as has been said, an attribute of sanity, just as is the existence of a reasonable motive, though both do often actuate the mind deranged. We should fall into a grave error, however, should we deny the possibility of other forms of insanity than those which I have excepted, being accompanied with either acts of feigning, or motives; an error which facts of daily observation among the insane fully prove.

The government of insane-asylum households, as every physician knows, is conducted upon the idea that the insane, like the sane, though in a degree more or less modified by disease, are actuated by ordinary motives, and can be kept within certain rational limits of conduct and expression by the conditional rewards and inducements to correct behavior there employed. The rude and indecorous often act with propriety when such a course is made the condition upon which they are permitted to take part in the amusements and religious exercises of the asylum, or to have other rational indulgences allowed them. Proper letters are written, and delusions suppressed by the writers thereof, in some instances, after the patients have learned that very insane letters are discountenanced by the superintendent, and returned to the writers for improvement in regard to their rational tenor. The love of absent wife or husband, father, son, or daughter, as the case may be, and the natural desire to communicate with them, sometimes leads to compliance with the superintendent's somewhat compulsory request, and to the expunging of all evidences of insanity from their letters, by the patients themselves; and at this point the re-establishment of the rational exercise of volition, in restraining and refraining from the expression of morbid fancies, sometimes commences, and the patient's convalescence begins.

The fact, therefore, that the insane are more or less influenced by rational restraints and motives, like the sane, though in an impaired and lessened degree, would seem to need no further illustration. All who have much observed them, know that they are constantly induced to do the above and other acts which may result in benefit to themselves. They not unfrequently pretend to have abandoned cherished delusions, and to have entirely recovered their reason, with the view of securing a premature discharge from the asylum; and even good judges of insanity among medical superintendents have sometimes been deceived by the plausible pretences of such patients, who, failing to convince the asylum medical-officers, have sometimes succeeded in getting the hearing of courts, and have been released on writs of habeas corpus, only to convince every one, after a time, of their perfect fitness for perpetual restraint.

The co-existence of insanity with the power of devising the most plausible explanations of erratic and insane conduct, is sometimes seen before courts of justice, as in the case of Col. M., District Attorney in one of the Southwestern States, under President Jackson, as detailed by Dr. Ray.[1] Mr. M. entertained the delusion that he was cousin to the Duke of Wellington, and to Napoleon; he cut off his own nose, and, after the rhinoplastic operation had been performed, cut out the cicatrix on his forehead whence the nasal flap had been taken. "He was a passionate, dangerous lunatic," according to Dr. Bell, and yet so plausible in explanation and extenuation of his conduct, and in defence of his personal

[1] Medical Jurisprudence of Insanity, 4th ed., p. 196.

and legal rights, that no asylum could hold, and no tribunal seriously punish him.

The celebrated suit of Wood *v.* Dr. Monroe, in England, for false imprisonment, as cited by Bucknill and other writers, also illustrates how a really insane person may succeed in concealing his mental weakness for a time from the most astute observers. The severest examination failed to detect Wood's mental infirmity until he was asked what had become of the Princess with whom he corresponded in cherry-juice, which immediately caused him to reveal his insanity, and he lost his case. Discovering the cause of his failure, he renewed the suit in London, and then all the ingenuity of the bar, and the authority of the court, could not elicit an exposure of his delusions, though he still entertained them.

The simulation of insanity would seem no more difficult than the assumption of sanity by the insane. If they can conceal, or explain away so as to deceive the best judges, mental defects which they actually possess, why may they not assume abnormal traits which they do not possess? In the corridors of an insane asylum we sometimes see one lunatic contemptuously or in sport caricaturing the whims and vagaries of another, all the while fancying himself the sanest of men, while he regards his brother lunatic as the simplest of simpletons, or the most knavish of knaves. "Amidst our criminal population, too, are hundreds who can hardly be said to be sane and responsible, but who, in the lower ranks of life, commit a succession of crimes of no great magnitude, which render them the almost perpetual inhabitants of jails. Some of them are so violent, outrageous, and destructive—so silly in their motiveless fury, and so childish in mind—that we may call them imbecile, or insane, and have good grounds for our opinion."[1] These are the illy fed and clothed, badly raised and housed, inhabitants of the densely populated portions of our large cities, or the neglected children of drunken, epileptic, or otherwise mentally maimed, parents, whose blood has been poisoned with alcohol, opium, nicotine, and the noxious vapors usually abounding where these cerebro-mental abortions come forth and grow up into dwarfed and diseased maturity. At the maternal fount they drink in disease, and are never afterwards entirely well—never perfectly sound in mind, and never able to act out a natural life. When these human abnormities grow up to manhood and womanhood, having led a life of deceit, we might reasonably expect to find them simulating insanity, as they sometimes do, when detected in, and incarcerated for, criminal acts, being all the while unconscious that they are already really victims of disease. This class should receive more careful examination, with a view to the discovery of simulation among its members. That many cases are not recorded, may be due to the fact that sufficient search for them has not been made, simulation by the actually insane not having, until a comparatively recent period, been conceded by writers. I can recall the names of no authorities more remote than Griesinger and Baillarger, who have admitted the possible co-existence of simulation with real insanity.

Armand Laurent,[2] as lately as 1866, gave several illustrative cases, especially in connection with imbecility. A case was reported in the *American Journal of Insanity* for 1863, but the most recent and unequiv-

[1] Blandford's Lectures, 1871, p. 390.
[2] Étude Médico-Légale sur la Simulation. Par le docteur Armand Laurent. Parie, 1866.

ocal recognition of the fact of simulation conjoined with actual disease, by high authority, is to be found in the report of the case of Michael Trimbur, in the number of the same journal for October, 1874.

It would be interesting to know what might have been the modification of Dr. Parchappe's view of the mental condition of Lambert, whose case is reproduced by Dr. Ray,[1] had the physician of the asylum at Rouen had in view the possibility of blended simulation with some remaining insanity. It will be remembered that Dr. Parchappe pronounced the case one of simulation of unconsciousness, after the prisoner had come to himself, in order the better to escape responsibility for his acts, he having, in a paroxysm, induced either by the virus or by the fear of hydrophobia, murdered his mistress and another woman without provocation, and giving as a justification for the homicidal act, in regard to the former of his victims, the insane reason that he desired to bestow her money in charity, which, he said, she would never have done had she lived. On the day of the murder, Lambert admitted killing his mistress, and repeatedly exclaimed, "Jesus my God, my fortune is made," and begged his captors to release him because, he said, he "had eight more murders to commit." On the following day he denied having killed his mistress, but said "if I did, I do not remember it." Four days after the murder he recognized the hatchet with which he had done the deed, but denied all knowledge of the murder. I do not offer this as certainly a case of simulation conjoined with insanity. It may or may not have been such, and, as my purpose is rather to elicit discussion than to advance positive opinions, I have deemed an allusion to it not out of place. Dr. Ray, in summing up this case, concludes that it was one of feigned insanity, while Dr. Parchappe, as we have seen, thought that it was an example of simulation after recovery. May not the simulation have begun before recovery had been completed, after a realization, upon the part of Lambert, that he had committed heinous crimes from the penalty of which there appeared to him no escape, except in assuming unconsciousness of his acts?

Cases like that of the criminal in the prison at St. Ange, as related by Prof. Monteggia and translated by Marc and Ray, and like that of Samuel S. Rich,[2] which occurred in this country, come to mind, in this connection, as having shown perhaps phases of simulation, which might have been revealed had the possibility of simulation co-existing with insanity been entertained by the profession in those times. There was no history of epilepsy in the case related by Prof. Monteggia, and though no such rigid search could have then been made for epileptiform complication as would be made now, there is not the slightest suggestion of anything of this character in the history of the case as it has come down to us.

It may not be transcending the limits of scientific propriety, to suggest simulation in connection with real insanity as a possible explanation of some of the features of the famous case of Joseph Waltz,[3] still fresh in the minds of all. There was undoubtedly simulation, and it was most bunglingly done; Waltz pretended to be suffering from dementia, which was certainly not the case. His "don't know" answers, made so often to interrogatories concerning facts which he clearly knew (such as the names of his mother and father, and his own age), and the post-mortem examination, clearly prove this point.

[1] Op. cit., p. 415.
[2] American Journal of Insanity, April, 1860.
[3] Ibid., July, 1874.

Just here the thought occurs, that when equally honest and experienced experts view a case, which they have had equal opportunities of observing, on the one hand as one of insanity, and on the other as wholly one of feigning, it may be reasonable to look for co-existent simulation and real disease, to explain the discrepancy of opinion. The case of Waltz also suggests another possibility, viz., that in some cases, the eagerness of counsel to make out a case of insanity from too meagre data, aided unintentionally by the suggestive questionings of the physicians who visit the prisoner at the counsel's request, may sometimes lead a prisoner, not in the beginning so disposed, to attempt feigning; and that if the sane may thus obtain an idea that simulation can be successfully practised, we need not be surprised to see the same thing undertaken by some real, though not pronounced, lunatics.

In a letter from Dr. Bucknill, referring to the case of Jesse Pomeroy, whom Dr. B. had visited with Dr. Edward Clarke in the jail at Boston, in April, 1875, the writer says "some physicians had suggested concealed epilepsy . . . . as the cause of this boy's blood-thirsty propensities, and had questioned him as to the existence of an *aura*. Whether this boy had got the idea into his head or not, I know not, but he told Dr. Clarke and myself that he often had the feeling that a light feather was drawn across his forehead from one temple to the other. Now, as Dr. Clarke remarked to me at the time, this is not the accurate description of an *aura*, which follows the course of nerves."

"Generally, after the acute stage has passed off, a maniac has no difficulty in remembering his friends and acquaintances, the places he has been accustomed to frequent, names, dates, and events, and the occurrences of his life. The ordinary relations of things are, with some exceptions, as easily and clearly perceived as ever, and his discrimination of character seems to be marked by his usual shrewdness."[1] His replies to questions may or may not indicate delusions or other extravagances of thought, while his whole demeanor and conversation may show that he has some appreciation of his previous mental condition, and a fair conception of his present surroundings. Under these circumstances, it is not difficult to suppose that a really insane person, finding himself arrested, and in the hands of the law, on the charge of murder or other crime, which he knows that he has been seen to commit, and from the penalty of which there seems to him no escape except through the plea of insanity, might conclude to simulate such a form of insanity as in his opinion would secure his exculpation. Such a person might not believe in the existence of his own real mental disease, and might fear that those who were to try him would be equally incredulous; the insane are not generally conscious of the extent and degree of their mental derangement. Admitting, then, the existence of a sufficient degree of rationality, in an insane person, to prompt to an effort at self-preservation through the act of feigning, would he probably assume a more exaggerated form of mental disorder, just as sane men usually do with the view of making a favorable impression, and with the customary result of over-acting and detection? We cannot reason out an answer to this question, and practical illustrations are too few to enable us to generalize on the subject.

An insane person, having once been an inmate of an asylum, would there have opportunity to become familiar with the ordinary character-

[1] Ray, op. cit., p. 390.

istics of insanity, and would not, I think, be so likely to assume the tragic and exaggerated forms of madness, as one more ignorant. His capacity to successfully reproduce what he had observed in the asylum, would depend upon the degree of mental soundness existing in him at the time at which he had been an inmate, and remaining with him at the time of attempted feigning. Insanity is a crippled, rather than a destroyed, or obliterated, mentality.

From the nature of insanity, we see that feigning is possible oftener than it is shown by experience to occur in connection with the usual forms of the disease. Insanity is an impairment of one or more of the mental faculties, by reason of disease involving the brain; and as it may exist in every degree, observing the same pathological laws as any other disease, it is evident that acts which in themselves are rational in character, may be done by the insane. A sick man is seldom so sick, unless it be in the last and hopeless stage of his malady, that he can do none of the acts which he could perform when well. Among the acts, therefore, which the insane must be deemed capable of performing, we must include simulation. It is not uncommon for the healthy human mind to dissemble, especially in civilized life; and this natural trait does not always wholly forsake the mind diseased, though it must be confessed that the insane wear less of a mask than the mentally sound, and thus we come again to the general truth as applied to the insane, *in maniâ veritas.* Some exceptions to this rule have come to my notice, and further observation may discover more; but not enough to invalidate the rule as applied to insanity in general: *Exceptio probat regulum.* A mental phenomenon worthy of note here, but not germane to the subject, is the unconscious or semi-conscious *imitation*, rather than simulation, of insanity, which is displayed on certain occasions by those who largely inherit the insane neurosis. It consists in a sort of sympathetic taking-on of an evanescent form of insanity by other members of a family, under great excitement, as when one of their number has become profoundly afflicted with some marked form of mental disorder. A father or mother, for instance, brings to the asylum a son or daughter, when, from the exaggerated and unnatural conduct of the parent, aside from the natural manifestation of grief to be looked for on such an occasion, but which is sometimes wanting, the superintendent finds it difficult to determine which for the time acts the most insanely, parent or child. The conduct of the parent appears anything but rational, yet a return to home, divested, in a measure, of anxiety and the weariness of watching, with a season of rest and sleep, and better appetite and digestion, suffice to restore the disturbed balance of the mental faculties, and the parent, by reason of regular life and habits, escapes the affliction of positive insanity, though possessing and transmitting a neuropathic diathesis but one remove from it.

Insanity, as Prichard observes, sometimes co-exists with an apparently unimpaired state of the intellectual faculties; though "the ideational portion of the faculties," as Blandford remarks, "is so intimately joined to the emotional, that the two must be sound together, or unsound together." Admitting the existence of so slight an intellectual aberration, in certain kinds of insanity, that the intellectual lesion is more theoretical than apparent, it is easy in such cases to concede the possibility of simulation on the part of the patient, to extenuate erratic and immoral conduct, the result of disease. The subjects of moral insanity sometimes simulate inebriety, as well as insanity, to palliate and excuse what ap-

pears to them and to others, not expert in detecting mental aberration, inexcusable conduct. The case of Col. M., already alluded to, was one of this kind; many of his freaks were excused and explained away, when they could not be denied, upon the plea that he had drunk a little too much on that particular occasion.

It is not easy to perfectly imitate diseases involving the mind in disorder, notwithstanding that Zacchias has said that feigning is easy, and detection difficult. The unconscious "method that is in madness, the constant and consistent reference to the predominant idea, which the practical observer detects amidst the greatest irregularity of conduct and language,"[1] requires all the mental faculties in their fullest vigor, and unimpaired by disease, for successful personation, and is then rarely successfully feigned before the eye of the physician who is experienced in detecting the true features of morbid mentality. While, therefore, we may concede the possibility of occasional successful feigning by the mind in full possession of all of its faculties, we should not expect the crippled mind of an insane person to deceive us, and the fact of simulation being detected should not preclude the possibility of co-existing insanity in any particular case.

Dr. Ray, in his report of the case of Trimbur,[2] says: "The criminal classes, to which most of these simulators belong, know as well as everybody else that the plea of insanity is one of the dodges whereby people now escape the punishment of their crimes, and they may not forget to act accordingly when they become insane themselves." This was the case with Trimbur, who, "being unconscious of his own real insanity, but with mind enough to understand his situation and to remember what he had heard about insanity in connection with crime, concluded to make a show of being crazy."

The following case, communicated to the writer by Dr. Joseph Workman, for many years the distinguished medical superintendent of the Toronto (Canada) Lunatic Asylum, seems equally illustrative of blended simulation and real disease, and, as it has never been published, I give it here in Dr. Workman's words:—

Some ten or twelve years ago, I met [says Dr. Workman] with a case of genuine simulation in a man who had murdered his wife. He had previously been a patient under my care, for about a year, when he undoubtedly was insane. Just as I was on the point of discharging him as recovered, he eloped. I did not use much exertion to recapture him. He went home to his farm, and got on well until his insanity returned, taking the form of jealousy of his wife, which, I need not say, was utterly causeless. One day, in the sugaring season, in the bush, he killed her with a billet of firewood. He was apprehended—did not in fact try to escape—admitted his crime, and was tried at the next assizes. I was summoned as an expert witness, and had a long interview with him in the jail before the trial. I knew him at first glance, and asked him if he did not remember me? He said that he did not; that he did not think that he had ever seen me. "Why, John," I said, "you must remember me well; you lived in the same house with me for over a year, and talked with me hundreds of times. You remember being in the asylum?" No! He had no such recollection, but people had told him that he had been there. "Well, you have not forgotten your old friend Mr. E., the steward?" He did not know him at all, and so on throughout all our colloquy. I had the most thorough conviction of this man's stupid mendacity and bootless simulation, and at the same time of his insanity at the time of committing the murder, and I stated both to the jury. He was

[1] Ray, op. cit., p. 388.

[2] American Journal of Insanity, October, 1874.

acquitted on the ground of insanity, and was committed to the asylum for criminals, at Kingston, where he is still detained.

Two or three years after his trial, as I was passing through the asylum in company with the medical superintendent, a patient stepped up and held out his hand, addressing me very courteously, and inquiring after all my family. I did not recognize him until the medical superintendent told me that he was my old friend J. C. "Oh! John," said I, "how is it that you know me so well to-day, but did not know me at all in Guelph jail?" His reply was, "I did not want to know you that time." This man had certainly a very powerful motive for simulation of mental frailty, but he played his part too unskilfully to impose on my credulity. Jealousy was not the *cause*, but the *form* of his insanity, and when he had forever got rid of the subject of his delusions, a sober after-thought assumed the government. He was, as I believed, still insane, yet possessing that degree of stupid cunning which not a few sane people evince. He knew that he would be hanged unless acquitted on the ground of insanity, for in Canada murderers generally have but little chance of escaping the death-penalty. Had he been thoroughly sane, he would have known that sufficient proof of his past insanity, both in the asylum and afterwards, could have been produced, and he would have abstained from his clumsy simulation, or he would have acted his part more cleverly. I could not say that he committed the common error of simulation—overdoing his work. He did not rave, babble, or declaim, or indulge in foolish antics and grimaces.

In criminal cases, when an individual, in whom there exists undoubted evidence of mental disease, actually pretends to have a form or symptoms of mental disorder not in harmony with the kind of insanity which actually afflicts him, or not in the natural course of his disease, the presumption is reasonable that there also exists in him a sufficient degree of rational volition and appreciation of surroundings to modify the degree of his responsibility to law. The perplexing question then arises as to whether the individual's state of mind at the time of feigning be the same that it was at the time of violating the law; the presumption is in favor of a clearer mind at the time of the simulation than at the height of the insanity, and this appears to have been the case with Dr. Workman's patient. The mind disturbed by disease, varies in the intensity and degree of its disordered manifestations at different times, even as the healthy mind is known to vary on different occasions in the display of its natural peculiarities and powers.

Other questions are here presented, of a medico-legal character, relative to criminal responsibility and testamentary capacity in certain cases, which, in the present state of our knowledge of psychology, cannot be satisfactorily answered in general terms. Eminent alienists all admit, in the abstract, the existence of different and variable degrees of rational capacity and responsibility in mental disorder. There are, as Locke says, "degrees of madness as there are of folly," but to determine precisely what amount of impaired mind-power exists in particular cases, may often puzzle the most learned and experienced psychological experts. The law has attempted to cut the Gordian knot, to untie which has so long baffled the most thorough students of the mind diseased, by deciding that the capacity to distinguish right from wrong, should settle the question of responsibility to law in criminal cases; but practically we know that an individual may clearly know right from wrong, and yet, under the overpowering influence of cerebral disease, be irresistibly impelled to do the wrong. The importunities of the insane to be restrained, when suggestions of violence, prompted by morbid states of the brain, arise in the mind, and when the patient's own recollection of his past

experience teaches him that resistance to his insane impulses beyond a certain limit is impossible, are familiar to all accustomed to come much in contact with the insane in asylums. The physiological fact of unconscious cerebration is applicable to the mental operations in disease, as well as in health, and to many acts of the insane, especially of the epileptic class, but certainly not to all. The legal test therefore fails, and indeed it has been much qualified of late in the rulings of the courts. We must concede, however, that this test can be justly extended much further than at first blush would appear to be proper, for unconscious cerebration in a paroxysm of insane fury would save many a lunatic who, a short time before or after, would fully comprehend the nature and quality of his acts.

The facts admitted in this digression would tend to prove the possibility of simulation by the insane, even if it were not established by experience; knowing, as many insane persons do, that they have unconscious states in which their irresponsibility is conceded by all, it would not be strange for an insane man to pretend to have been in such a state, when he really had not, to escape censure or punishment for some act which he knows that he ought not to have done, and the impulse to do which he knows that he could have resisted. I do not now allude to those acts of the insane which, from their history, we might expect them to commit, such for instance as suicide in the suicidal form of madness, homicide in the homicidal, burning in the pyromaniacal, stealing in the kleptomaniacal, etc.

There is one fact which might in some instances deter insane persons from feigning, even when the disposition and capacity existed, and that is the knowledge which they possess of the estimation in which they are held, as irresponsible. Who, accustomed to live with the insane and thus made familiar with their true character, does not know how keenly conscious they are of the existence of this erroneous estimate of their real condition as regards responsibility, removed, as they are in the asylum, from those sources of irritation which have caused, or which tend to keep fresh opened, their mental wounds? A patient once told me that he would have his liberty, or kill me. I said, "Then you would be hanged." He answered, "They could not do that, I am insane." "But," said I, "you would not be insane on that subject. You know it would be wrong, and your insanity is not homicidal." He said, and said truly, "No jury would ever hang a lunatic for anything that he might do in an insane asylum." Not being able thus to intimidate him, I approached him ever afterwards with caution, and always dodged, when practicable, the discussion of the question of his personal liberty. This patient used the word lunatic sneeringly, for, though admitting that he was not always right in his mind, he did not consider himself seriously insane, though, at times, he was really very much so, his paroxysms of excitement lasting many days at a time. It is easy to conceive of circumstances under which such a patient might simulate, as well as rely upon, his reputation for insanity.

The fact of unconscious cerebration, before alluded to, as we see it manifested in cases of hysteria, mingled with conscious and partly volitional, mental activity, explains the simulation of real insanity which sometimes co-exists with this singular morbid state. In hysterical insanity, there seems to be a morbid desire to act out actually controllable vagaries, as well as those really insane promptings which are beyond the control of the will. The insane of hysterical tendencies often act in

a seemingly controllable, but very insane, manner, apparently through a morbid craving for extraordinary sympathy and attention. Occasionally, however, their actions are apparently wholly motiveless, as with other and aggravated forms of insanity.

Though simulation is rarely practised without motive, it is possible for the motive to be sometimes a very foolish one, and, while it may be unaccompanied by delusion, yet scarcely explainable upon the hypothesis of perfect sanity. Such a case would lead to great perplexity in the mind of the physician.

The egotistic feeling so often uppermost in the mind diseased, causing the insane to seek in so many ways to attract attention, or excite wonder and commiseration, is only an exaggeration of a not uncommon, natural trait of rational minds. It may be donbted whether the case reported by Dr. Bell, an abstract of which may be found in Dr. Ray's[1] excellent work on the jurisprudence of insanity, was without real disease as well as blended simulation. Dr. Ray, in introducing the case, regards it as "somewhat curious, considering the youth of the subject, the apparent want of motive, and the severity of the symptoms."

The lad, thirteen years old, had fallen on his head two years previous to admission, and ever since that period had exhibited some anomalous symptoms of disease, which had been referred by his physicians to derangement of the digestive organs. For the last few months, the symptoms had been more severe and decided. He had refused food for long periods, had had spasms, had lain with his eyes fixed and his legs drawn up, would hold his breath and strike. On admission to the asylum, he presented the appearance of a sickly, emaciated boy, under puberty, unable to stand, exhausted by suffering, breathing quickly, and passing his evacuations in bed. Every few minutes he had a frightful spasm, commencing with a convulsive shaking of the head, pawing of the hands, and turning up of the eyes. Soon his hands would vibrate against his sides and chest, his countenance would be dreadfully distorted, and then would commence a horrid scream that might be heard over the whole premises. In this condition, with occasional remissions, and the addition, at one time, of diarrhœa, he remained for about a month. . . . Being watched through a hole in a blanket hung before his window, he was observed to jump up and stride about his room as actively as any body, but at the slightest noise resumed his old position, screaming and groaning.

Dr. Bell broke in upon him before he could regain his bed, chided him for his deceit, and bade him walk into the hall. "The spell is broken," says the record, "the feeble knees are made strong, the convulsed and distorted visage is calm and smooth, and the young deceiver goes forth clothed and in his right mind." Dr. Chipley, commenting on this case,[2] says, "We can scarcely conceive that one would assume a character so painful to sustain, without some deliberate purpose, or an end to be accomplished;" and yet no motive such as might be supposed to actuate the rational mind, is at all apparent in this case. The fact of the boy's having refrained from his usual manifestations on the unexpected appearance of Dr. Bell, whom he doubtless held in no small degree of awe as the all-powerful head of the establishment, while it proves a power of control over the actions under great external influences, and is strongly presumptive of feigning, does not, to my mind, conclusively establish the fact of entire sanity. There is nothing absolutely incompatible with insanity in sudden cessation of its symptomatic manifestations. If this youth

[1] Op. cit., p. 405.

[2] American Journal of Insanity, July, 1865.

was willing to make such continued, great, and painful sacrifices of comfort and character for the ridiculous and unreasonable purpose of exciting wonder and commiseration, such a motive, coupled with the youth's history and all the attendant circumstances, is well calculated to excite our suspicions as to his entire mental soundness. There were at the time, doubtless, others in the hospital more insane than this boy, and perhaps others, regarded as undoubtedly insane, who were fully as rational as he. A good deal of sanity may still exist among those who are too insane to mingle with the rational world.

Visitors, passing through the corridors of a hospital for the insane, often remark this fact, and the asylum-officers are often asked why certain patients are restrained of their liberty, because of their presenting to the casual observer so little appearance of insanity. So proper are the manners and conversation of patients, at times, that an unfounded distrust of public hospitals for the insane has sometimes been engendered in the public mind from this source—the insane themselves behaving so well in the presence of visitors, and at other times, under the present wise and scientific system of classification, medical and moral management, and restraint—the latter, in this country as in England, hardly exceeding non-restraint.

It would unduly lengthen this paper to detail the many instances which might be gathered of insane persons, on certain great occasions which made profound impressions upon their minds, having behaved with unaccustomed propriety, and having suspended for the time-being all manifestations of insanity, or to mention instances of great and unexpected events having been the beginning of recovery. Every one accustomed to the care of large bodies of the insane, knows that grand and unusual occurrences, which would startle and profoundly impress the rational mind, sometimes favorably impress the insane, notwithstanding that, in the main, they are either regarded with indifference, or cause aggravation of existing excitement. Some instances in point might be mentioned in connection with the burning of asylums. No such event has ever happened in my own experience, but the burning of a large stable and barn on the asylum premises at Fulton, early one evening, in full view of a good portion of the patients, gave opportunity to witness, in some degree, the different conduct of different lunatics under such circumstances. A very few of the patients were more excited than usual; the majority were indifferent; and some gave us valuable aid in our efforts to suppress the flames and save the stock.

The coercive methods of treatment, recommended and practised by Celsus, demonstrated the power of self-restraint in some cases, under the influence of overmastering fear; and in our own day, threats and punishments, though for obvious reasons neither practised nor advised as curative agencies, are not without some influence in subduing some refractory and noisy patients into submissive silence, as may be learned by visiting some of the almshouses and jails to which many of these unfortunates are yet consigned in the United States. It may be conceded that to be influenced by fear to such an extent as to suspend all display of insanity, is, in some cases, good evidence of feigning; but it must not be so regarded in all. Fodéré has been criticized, by a writer from whom I have already quoted,[1] for having relied upon the test of fear in the case of a female, who acted her part, if she were only acting,

[1] Dr. Chipley, American Journal of Insanity, July, 1865.

so perfectly that the doctor was on the point of certifying the case. He returned to her door, however, and said with a stern voice, "To-morrow I will visit her again, and if she continue to howl, if she be not dressed, and her chamber not put in order, you must apply a red-hot iron between her shoulders." He found things in order the next morning, and on this proof alone, with strong evidence to the contrary, immediately decided that it was a case of simulation. "But was this decision justified," asks the writer, "by the simple fact that the patient changed her conduct under the terror inspired by severe threats?" And he answers the question by referring to the self-control exercised by patients under the influence of fear, or the hope of reward. The potency of authority in suddenly suppressing through fear all appearances of mental derangement in those who are really insane, is, of course, exceptional; I can hardly conceive of such instrumentalities being successful in aggravated cases of general cerebro-mental disease, yet their occasional influence in controlling the less general forms of insanity, especially where simulation co-exists, is not to be doubted.

In hospitals for the insane, the power of one having authority is sometimes shown in the restraint which some patients put upon morbid and quasi-morbid displays, in the presence of the chief physician, and the arrest of paroxysms of hysteria by commands and threats, before the disease has reached the point of recognized insanity, is nothing new to the profession at large. This characteristic of partial control under ordinary circumstances, reaching the point of entire control under extraordinary circumstances, in cases of hysterical insanity, is too familiar to the profession to need further notice; it extends also, as I have endeavored to show, to other cases.

The power of self-restraint implies the power of simulation. Hysterical patients are undoubtedly more prone than others to "put an antic disposition on," as Hamlet has it, and are more disposed to act insanely than to exercise aright what power they really possess of at least restraining within more rational bounds the ridiculous displays which they often make.

The following case presents, I think, some interesting features:—

Reuben S., æt. 25, married, of limited education and of intellect below the average,[1] with a history of domestic infelicity, masturbation, and three weeks' insanity before admission, entered the Missouri State Lunatic Asylum on April 6, 1867, and was discharged, recovered, on November 15 of the same year. He had been an *attaché* of a sort of travelling circus, and theatrical and minstrel troupe, before the development of his insanity. After becoming insane, he had been seized with a sudden desire to preach, and, securing an audience in one of the country towns of Missouri, he conducted the services in such an obscene, blasphemous, and outrageous manner, that he was driven from the pulpit. His insanity becoming apparent to the neighborhood soon after, he was sent to the asylum.

At the asylum he endeavored to preach in the same way, but being put into an empty, quiet room, with a single window looking out on the lawn, and no audience, he soon grew tired of addressing vacancy, and changed his performances to tearing up his bedding and clothing, and soiling the walls and floor of his room. His occupation in the corridor changed to negro minstrelsy of the most ridiculously insane character, mingled with some really good hits at men and things which he had learned. He was fond of applause, and much

[1] I doubt this statement as to his natural intellect. His history was not given by near relatives or by those who had known him long.

encouraged when he excited laughter. The manner and intensity of his performances could be very much varied by our signification of approval or disapproval. He would seriously hurt himself, if permitted, in his attempted feats of ground and lofty tumbling. I never had the slightest doubt of his insanity, and have not to this day.

This patient's propensity for acting, after he had come to eat and sleep well, gradually wore off, but, during his convalescence, the least encouragement from officers or attendants would start him to performing. To keep him quiet, it was necessary that no notice should be taken of his antics, and the attendants were instructed accordingly. After his discharge from the asylum, he went to a distant part of the State, but soon returned to Fulton, and engaged in the business of a barber. He did not change his name, but denied ever having been in the asylum, though all the attendants knew him as our former patient, and often met him. He conducted his business properly enough, as far as I know, but the attendants who visited him, none of whom he would ever recognize, still thought him insane. It soon got noised about that he had been an inmate of the asylum, and he and his brother, who was also his partner, left for other parts.

There was no reason for believing this man to be wholly feigning. There were no charges of any kind against him, and no friends were interested in having him shielded from any punishment; moreover, he made several clever attempts to escape, at one time remaining away for a whole day before being recaptured. It is true that his performances were mainly given when he could get an audience, and were prompted by love of applause and notice; but he slept very little, when not narcotized, and occupied himself at all hours of the night in tearing his blankets, littering his room with straw, and doing every conceivable mischief, in addition to soiling his room and person. Before we had concluded to employ the necessary restraint, he was always doing something ludicrous or destructive, and the poor fellow's antics and appearance excited more laughter than any other patient on the male side of the house. When he came to the asylum he was extremely emaciated, indifferent to food, and, indeed, to everything except notice and applause. Egotism was constantly uppermost with him. His pulse was quick, and he was never known to be quiet while awake. As he convalesced he grew quiet and thoughtful, his pulse became slower, and he slept better, and improved in appetite and flesh.

This case was certainly a remarkable one: Could any conceivable motive have been found, we should have suspected simple feigning. The patient was evidently not aware that he was acting the part of a lunatic to an audience of insane persons, and in this respect the case differs from others, the simulator, sane or insane, generally appreciating, in some degree, the nature and extent of his acting and surroundings. Still the case serves to show the power which the insane possess of acting somewhat for a purpose, much after the manner of other people.

Though a mania for display is not uncommon with the insane, its appreciable modification by the applause or disapproval of those about the patient, would be taken, in most instances, for pure feigning without the co-existence of cerebral disease. Everything in this case but the one fact of the patient's acting most insanely when most observed, contradicted the notion of feigning. His physical condition, his antecedent history, the nature of his acts, and, after recovery, his changed demeanor, all pointed to the existence of real insanity.

I turn now briefly to a class of cases regarded by many as more devilish than lunatic, viz., the morally insane; who know how they are considered, and why they are in the asylum, and who take advantage of their reputed insanity to do many things from which they might perhaps refrain if they chose, but to which disease really prompts them. They

sometimes pretend to a degree of intellectual impairment not natural to them in their diseased condition.

These patients know where they are and why they are there, and to a certain extent are able to behave themselves with propriety when motives are powerful enough to induce them to do so, particularly under the absolute authority which they know that they have over them at the asylum—exercised, it is true, in the mildest and least irritating way, but usually with firmness and certainty. At home, with those whom they have been accustomed to manage, they are uncontrollable, and behave themselves like very devils, so that they get no sympathy. The world outside does not understand them, and cannot get along with them, and indeed those in charge of asylums wish that these patients could be cared for elsewhere.

With distorted views of men and things about them, just short of delusion; dissatisfied and suspicious, often without the shadow of a cause; sometimes devoid of affection and gratitude; sleeping and eating poorly; never in a state of mental composure, but always quarrelling with the cook, the laundress, the attendants, or some fellow-patient; with bowels often habitually constipated, circulation disturbed, and general appearance of ill health, if these patients are insane—and I think that they are—they can also simulate to an aggravating degree, when it serves their purpose, abnormal mental states not actually existing in them.

The possibility of self-control under exceptionally powerful external influences coming to the aid of the will of persons reputed to be insane, does not preclude all possibility of the existence of real insanity. A more or less modified power of self-control exists in the incubative stage of most forms of insanity, even under ordinary circumstances, and persists oftentimes until the case has passed into the form of final and hopeless dementia. After recovery, our patients sometimes tell us how they resisted morbid promptings to extravagant words and conduct, before these found unwilling and resistless expression. Suicides and homicides by the insane are seldom without premonitory preparations, threatenings, and warnings, and much of the freedom of intercourse, coupled with safety, of asylum-life is due to this fact. Even in cases of well-advanced insanity, morbid impulses of various kinds are sometimes long and repeatedly resisted before their final consummation.

The power to restrain and suppress insane promptings, so frequently exhibited by the insane, implies the power to simulate the features of insanity. In all asylums for the insane, there are chronic cases in which the original delusion, though still persisting, ceases to dominate the patient as in the beginning—cases in which the aggravated demonstrations and exclamations of the patient are disproportionate to his delusion. The insane man's oft-repeated actions and expressions become a sort of second nature, as habit becomes with the sane. There is a kind of automatic simulation here; these patients act out a state of feeling which is not real to them. If once tormented with a painful delusion, they cease to suffer as acutely as in the beginning, if they suffer at all, and their attention is more easily diverted from self.

Our asylums afford many examples in which the patients, yielding more or less to their delusions, also more or less modify or suspend the expression of them. This fact is illustrated and recognized in the moral treatment of the insane. Even sane persons are not free from dissimulation, and while insanity in the main reverses the natural charac-

ter, it sometimes throws off the natural disguise put upon the conduct and conversation in health; thus we may find the natural disposition to dissemble, in not very profound forms of mental disease, displaying itself less guardedly than in health. Hysteria is an apt illustration of this fact, both before and after it becomes actual insanity.

The insane, like the sane, though on the whole more truthful than the latter, are not always and altogether what they seem in acting out their real psychic impulses. They are sometimes more crazy than they appear, and sometimes appear more insane than they really are. We have generally to scrutinize an insane character closely to fully comprehend it. Esquirol's estimate of the value of constant observation, in order to become familiar with the subject, expressed very nearly the truth: We must live with them to fully know them. Simulation of insanity may exist in connection with actual psychical defect, the result of disease of the brain, just as disease of the stomach, lungs, or other organ, may be accompanied with a greater or less degree of healthy function. Only death obliterates and destroys all function, while disease, short of death, modifies and perverts organic activity.

Physical disease, involving the so-called physical organs in contradistinction to the organ of the mind, is not always or usually entire physical destruction; and so disease involving the mind and its organ, is not always or usually entire mental overthrow or obliteration; rather is the latter the exception, than the rule. Do we not, therefore, err, if we seek to find in every case of apparent mental aberration all simulation, or all insanity? Is there anything in the nature of insanity, as we recognize its different forms, incompatible with simulation? I think not, except it be in profound and advanced general mania and dementia; and from this cursory survey of a field which grows wider as we view it, I conclude that it is not only not impossible for the insane to simulate insanity, for a purpose, in any but its graver forms of profound general mental involvement, but that they do sometimes actually simulate acts and forms of insanity for which there exists no pathological warrant that can be discovered in the real disease by which they are affected.

Discussion on Dr. Hughes's Paper.

After the reading of the preceding paper, Dr. Isaac Ray, of Philadelphia, said:—Until the present century, insanity was seldom put forth as an excuse for crime. Its frequent occurrence in our day has made it a duty of physicians to make themselves acquainted with its phenomena far more accurately than was before required. It often becomes their duty to say, in a matter of life or death, whether a certain person is sane or apparently insane, and, if the latter, whether the apparent insanity is real or simulated. Most of the insane know as well as other people that insanity is an excuse for crime, and there is no reason why they may not strive to use it as such, when occasion calls, by feigning some manifestations of the disease over and above those belonging to their own particular form of the malady. To do this requires no more shrewdness and self-command than it does to conceal their delusions, as they sometimes do. The fact that they are already insane does not preclude the need of simulation, for the well-known reason that the insane generally do not recognize their own infirmity. To them, the need of the excuse seems just as strong and just as apparent as it would to others.

Dr. Hughes's mention of Dr. Bell's case calls to mind a form of mental dis-

order, not unfrequently met with in general practice, in which the real and the simulated are curiously mingled together. It occurs mostly in women, beginning usually in a morbid fondness for sympathy, and for the attentions bestowed on the sick and suffering, and originating either in some hysterical condition, or in a decidedly insane temperament. There is nothing which persons thus disposed will not endeavor or endure, and the aches and ails which they affect, from a simple cough to fits and dislocations, no man can number. We are all familiar with them, no doubt. I knew of one who, not content with keeping a couple of watchers up all night for months together, would, when at all displeased, dislocate her jaw; and another who would, under similar circumstances, dislocate her hip. In such cases there is, undoubtedly, much mental disease, and also much downright simulation. And it is not always easy to determine what is to be attributed to the one, and what to the other, while a mistake may lead to great wrong and suffering. I call to mind the case of a young girl of some culture and refinement who kept her bed more than a year, unable to move without assistance, and regarded by friends and physicians as extremely ill. At last some one, walking in the garden, observed her, through a window in her room, rise from the bed and jump about as lively as a cricket. Of course there was an end to this sort of performance, but there soon appeared a good deal of mental disorder, which finally made her so troublesome that she was placed in our hospital. There, for weeks together, she behaved with the utmost propriety, evincing neither in conduct nor in conversation the slightest sign of insanity. This condition would alternate with periods when she lay in bed, unconscious apparently of everything around her, her face highly flushed, and her pulse fast and full. She took food only through the tube, and passed her evacuations in bed. From us she passed into the charge of an Indian doctor, by whom, it was said, she was cured. Some light is thrown on the psychological history of this case by the fact that a brother and sister were spiritualists, and that her mother presented many indications of the insane temperament. Now, had this young woman committed a criminal act, I fear that the plea of insanity would have availed her little in view of this instance of detected simulation.

ON THE BEST MODE OF PROVIDING FOR THE SUBJECTS OF CHRONIC INSANITY.

BY

CHARLES H. NICHOLS, M.D.,

SUPERINTENDENT OF THE GOVERNMENT HOSPITAL FOR THE INSANE, WASHINGTON, D. C.

MAN lives by reason; the brute by instinct. The greater size and complexity, and the higher organization, of the organs of reason, render them more susceptible to derangement than those of instinct; while the complex necessities, motives, and struggles, which belong to a life of reason, evolve the numerous exciting causes of such derangement just in proportion as the reasoning being develops his pre-eminent intellectual powers, and puts his feeble instinct into abeyance. When reason or motive is perverted by cerebral disorder or defect, man is both a dependent and an aggressive being. The utter incapacity to provide for himself which causes him to be regarded as an infant, in the eye of the law, is more apparent because of its most frequent occurrence at a time of life when he is most independent in his normal powers, and when both his absolute and artificial wants are most numerous and pressing. Intensity of purpose and action is often in direct ratio to perversion of judgment or motive, and the insane man is not only disqualified for providing for his numerous wants, but has the inclination and power, if left to himself, to be exceedingly dangerous to life and property.

Insanity is a term used to express the mental symptoms of a physical disease or defect which generally admits of partial relief, and which often admits of entire cure. If cured, the subject of the disease regains all his inestimable, human prerogatives—the ability to mingle in society, and freedom to will and to do of his own good pleasure. If relieved, as far as each case admits of relief by the diligent and skilful use of the appliances of modern science and benevolence, a life of sickness and privation is rendered comfortable and often measurably happy. Such a helpless, dangerous, privative, and yet remediable when not curable, infirmity, appeals not only to the deepest sympathies, but to the self-interest of the whole race among which it prevails. Insanity is everywhere regarded as the chief ill to which flesh is heir; and it is the sentiment of enlightened Christendom, however imperfectly and variously that sentiment may be expressed, that the insane of all classes should have all their needs provided for, because they cannot provide for them themselves; should have the medical and moral treatment that will alleviate, if not cure, their grievous disease; and should, as a rule, be restrained of their liberty, because it is unsafe for them to be at large.

If not cured, the pathological conditions of the brain which give rise to mental derangement, rapidly pass into a chronic condition, whose average duration is about equal to one-half of the mean length of human life. The result of efforts to establish by observation and pathological research the relations between the duration of mental disease and its curability, is the practice of classifying cases of not more than one year's duration as recent and presumptively curable, and those of more than

one year's standing as chronic and probably incurable. Experience shows that this generalization is useful in estimating the tendencies in respect to recovery, or duration of illness, of large masses of the insane, and the provisions required for their proper maintenance and treatment; but when it is considered that, under the circumstances most favorable to recovery, about fifty per cent. of all the cases of insanity that occur in a community pass this arbitrary boundary-line which has been set to divide recent from chronic mental disease, while the rapidly diminishing probabilities of recovery are not found to be extinct in individual cases until the expiration of the third or fourth year after the invasion of the malady, it will be seen that such a generalization can be only an approximation to the truth, with many exceptions. As the recent insanity of a community imparts an increment of not far from fifty per cent. of all the cases that annually occur, to those of technically chronic mental disorder, while an uncertain period of several years expires before individual cases become hopeless, the two classes are, for a considerable period at least, inseparably linked with each other, and either a philosophical or a practical consideration of "the best mode of providing for the subjects of chronic insanity," should obviously form a harmonious part of a comprehensive scheme of providing for the treatment of insanity of every duration and form.

In the year 1866, the Association of Medical Superintendents of American Institutions for the Insane,[1] a body of the highest acknowledged authority in America in relation to the wants and claims of the insane, after an exhaustive discussion of the exact subject of this paper, adopted the following five propositions, the first four unanimously, and the last one by a considerable majority of the members present at the meeting of that year:—

I. The large States should be divided into geographical districts of such size that a hospital, situated at or near the centre of each district, may be practically accessible to all the people living within its boundaries, and available for their benefit in case of mental disorder.

II. All State, county, and city hospitals for the insane should receive all persons, belonging to the vicinage designed to be accommodated by each hospital, who are affected with insanity proper, whatever may be the form or nature of the bodily disease accompanying the mental disorder.

III. All hospitals for the insane should be constructed, organized, and managed, substantially in accordance with the propositions adopted by the Association in 1851 and 1853, and still in force.[2]

[1] Including those of the United States of America and of the Provinces of the Dominion of Canada.

[2] Propositions offered by Dr. Kirkbride, and adopted at the meeting of the Association of Superintendents held in Philadelphia, May 21, 1851:—

(1) Every hospital for the insane should be in the country, not within less than two miles of a large town, and easily accessible at all seasons.

(2) No hospital for the insane, however limited its capacity, should have less than fifty acres of land devoted to gardens and pleasure grounds for its patients. At least one hundred acres should be possessed by every State hospital, or other institution for 200 patients, to which number these propositions apply unless otherwise mentioned.

(3) Means should be provided to raise ten thousand gallons of water, daily, to reservoirs that will supply the highest parts of the building.

(4) No hospital for the insane should be built without the plan having been first submitted to some physician or physicians who have had charge of a similar establishment, or who are practically acquainted with all the details of their arrangements, and having received his or their full approbation.

(5) The highest number that can with propriety be treated in one building is 250, while 200 is a preferable maximum.

IV. The facilities of classification or ward separation possessed by each institution, should equal the requirements of the different conditions of the

(6) All such buildings should be constructed of stone or brick, should have slate or metallic roofs, and, as far as possible, should be made secure from accidents by fire.

(7) Every hospital having provision for 200 or more patients, should have in it at least eight distinct wards for each sex, making sixteen classes in the entire establishment.

(8) Each ward should have in it a parlor, a corridor, single lodging-rooms for patients, an associated dormitory communicating with a chamber for two attendants, a clothes-room, a bath-room, a water-closet, a dining-room, a dumb-waiter, and a speaking-tube leading to the kitchen or other central part of the building.

(9) No apartments should be provided for the confinement of patients, or as their lodging-rooms, that are not entirely above ground.

(10) No class of rooms should ever be constructed without some kind of window in each, communicating directly with the external atmosphere.

(11) No chamber for the use of a single patient should ever be less than eight by ten feet, nor should the ceiling of any story occupied by patients be less than twelve feet in height.

(12) The floors of patients' apartments should always be of wood.

(13) The stairways should always be of iron, stone, or other indestructible material, ample in size and number, and easy of ascent, to afford convenient egress in case of accident from fire.

(14) A large hospital should consist of a main central building, with wings.

(15) The main central building should contain the offices, receiving rooms for company, and apartments, entirely private, for the superintending physician and his family, in case that officer reside in the hospital building.

(16) The wings should be so arranged that if rooms be placed on both sides of a corridor, the corridor should be furnished at both ends with movable, glazed sashes, for the free admission of both light and air.

(17) The lighting should be by gas, on account of its convenience, cleanliness, safety, and economy.

(18) The apartments for washing clothing, etc., should be detached from the hospital building.

(19) The drainage should be under ground, and all the inlets to the sewers should be properly secured, to prevent offensive emanations.

(20) All hospitals should be warmed by passing an abundance of pure, fresh air, from the external atmosphere, over pipes or plates containing steam under low pressure, or hot water, the temperature of which at the boiler does not exceed 212 degrees Fahr., and which are placed in the basement or cellar of the building to be heated.

(21) A complete system of forced ventilation, in connection with the heating, is indispensable to give purity to the air of a hospital for the insane, and no expense that is required to effect this object thoroughly, can be deemed either misplaced or injudicious.

(22) The boilers for generating steam for warming the building, should be in a detached structure, connected with which may be the engine for pumping water and for driving the washing apparatus and other machinery.

(23) All water-closets should, as far as possible, be made of indestructible materials, be simple in their arrangement, and have a strong downward ventilation connected with them.

(24) The floors of bath-rooms, water-closets, and basement-stories, should, as far as possible, be made of materials that will not absorb moisture.

(25) The wards for the most excited class should be constructed with rooms on but one side of a corridor not less than ten feet wide, and the external windows should be large, and should afford pleasant views.

(26) Wherever practicable, the pleasure grounds of a hospital for the insane should be surrounded by a substantial wall, so placed as not to be unpleasantly visible from the building.

The following propositions, also offered by Dr. Kirkbride, were adopted at a meeting of the superintendents held in Baltimore, May 10, 1853:—

(1) The general controlling power of a Hospital for the Insane should be vested in a board of trustees or managers: if of a State institution, selected in such manner as will be likely most effectually to protect it from all influences connected with political measures or political changes; if of a private corporation, by those properly authorized to vote.

(2) The board of trustees should not exceed twelve in number, and should be composed of individuals possessing the public confidence; distinguished for liberality, intelligence, and active benevolence; above all political influence; and able and willing faithfully to attend to the duties of their station. Their tenure of office should be so arranged, where

several classes received by such institution, whether these different conditions be mental or physical in their character.

V. The enlargement of a city, county, or State institution for the insane, which, in the extent and character of the district in which it is situated, is conveniently accessible to all the people of such district, may be properly carried, as required, to the extent of accommodating 600 patients, embracing the usual proportions of curable and incurable insane in a particular community.

No one of these propositions has since been either repealed or modified, and the experience of the ten years which have elapsed since they

changes are deemed desirable, that the terms of not more than one-third of the whole number shall expire in any one year.

(3) The board of trustees should appoint the physician, and, on his nomination, and not otherwise, the assistant physician, steward, and matron. It should, as a board or by committee, visit and examine every part of the institution, at frequent, stated intervals, not less than semi-monthly, and at such other times as it may deem expedient, and should exercise so careful a supervision over the expenditures and general operations of the hospital, as to give to the community a proper degree of confidence in the correctness of its management.

(4) The physician should be the superintendent and chief executive officer of the establishment. Besides being a well-educated physician, he should possess the mental, physical, and social qualities to fit him for the post. He should serve during good behavior, and should reside on, or very near, the premises, and his compensation should be so liberal as to enable him to devote his whole time and energies to the welfare of the hospital. He should nominate to the board suitable persons to act as assistant physician, steward, and matron; he should have the entire control of the medical, moral, and dietetic treatment of the patients, and the unrestricted power of appointment and discharge of all persons engaged in their care; and should exercise a general supervision and direction of every department of the institution.

(5) The assistant physician or physicians, where more than one are required, should be graduates of medicine, of such character and qualifications as to be able to represent and to perform the ordinary duties of the physician during his absence.

(6) The steward, under the direction of the superintending physician and by his order, should make all purchases for the institution; keep the accounts; make engagements with, pay, and discharge those employed about the establishment; have a supervision of the farm, garden, and grounds; and perform such other duties as may be assigned him.

(7) The matron, under the direction of the superintendent, should have a general supervision of the domestic arrangements of the house, and, under the same direction, do what she can to promote the comfort and restoration of the patients.

(8) In institutions containing more than 200 patients, a second assistant physician and an apothecary should be employed, to the latter of whom, other duties, in the male wards, may be conveniently assigned.

(9) If a chaplain be deemed desirable as a permanent officer, he should be selected by the superintendent, and, like all others engaged in the care of the patients, should be entirely under his direction.

(10) In every hospital for the insane, there should be one supervisor for each sex, exercising a general oversight of all the attendants and patients, and forming a medium of communication between them and the officers.

(11) In no institution should the number of persons in immediate attendance on the patients be in a lower ratio than one attendant for every ten patients; and a much larger proportion of attendants will commonly be desirable.

(12) The fullest authority should be given to the superintendent to take every precaution that can guard against fire or accident within an institution, and to secure this an efficient night-watch should always be provided.

(13) The situation and circumstances of different institutions may require a considerable number of persons to be employed in various other positions; but in every hospital, at least all those that have been referred to, are deemed not only desirable but absolutely necessary, to give all the advantages that may be hoped for from a liberal and enlightened treatment of the insane.

(14) All persons employed in the care of the insane should be active, vigilant, cheerful, and in good health. They should be of a kind and benevolent disposition, should be educated, and in all respects trustworthy, and their compensation should be sufficiently liberal to secure the services of individuals of this description.

were adopted, has fully established their sonndness and practicability (except, possibly, in respect to the last, which fixes an arbitrary maximum number of patients that may be accommodated in one institution), not less than ten States and one Province, if not more, having proceeded to provide for their insane upon the principles which they enunciate, and to embody them in their statutes. As I have intimated, the best provision for the subjects of chronic insanity should be embraced in a comprehensive plan of providing for the insane of all classes. The above propositions were intended to embrace such a plan, and, as I was their author, it will suit my convenience in the treatment of this question to attempt to reproduce the considerations that led to the views which they express: and perhaps this mode of presenting the matter will be more satisfactory to the Section, and more useful to the public, than any other. I propose to consider the propositions *seriatim*, and to lay particular stress upon the bearing of each upon the care of the subjects of chronic insanity.

The first proposition declares that "the large States should be divided into geographical districts of such size that a hospital situated at or near the centre of each district, may be practically accessible to all the people living within its boundaries, and available for their benefit in case of mental disorder." The obvious purpose of this is to affirm that institutions for the insane must be within the reach of the people whom they are intended to accommodate, in order that their insane may be sent to them; and it was framed in view of the fact that many hundreds of persons suffering from acute insanity had not received the hospital treatment that had been provided for them, and had consequently run into the hopeless stages of the disease, because of the long, fatiguing, and expensive journeys necessary to reach either the nearest hospitals, or those to which they were entitled to go. It is obvious that the principles of this proposition lie at the very foundation of an adequate provision for the insane, whether the form of their disease be recent or chronic. In an article on "The Use of Insane Hospitals," in the number of the Journal of Insanity for January, 1866, by Dr. Edward Jarvis, will be found a table which shows that, in the course of a series of years, twenty-two institutions in the United States and the Dominion of Canada received annually an average of one patient to 3974 of the population of the districts in which they were situated, and that the ratio of patients to population constantly and rapidly diminished in every case as the distances from the institutions increased, until an average of only one patient in 18,978 of the population of the fourth tier or belt of counties from the hospital centres, was sent to them. It is not reasonable to suppose that institutions for the insane breed insanity in the populations immediately surrounding them, nor that insanity is of more frequent occurrence in their near neighborhood than in more remote districts, and hence the only reasonable conclusion is that the remote districts were, solely on account of their remoteness, to a great extent deprived of the use of hospitals. This less use of hospitals by distant districts, is doubtless in some part due to the less acquaintance with their management and benefits than is acquired by people situated nearer to them, but in greater part to the disinclination of public authorities, and the inability of friends, to incur the expenses of transporting patients long distances with the necessary escorts, and to the apprehended danger to the lives of delicate persons from the exposures and fatigues of a protracted journey.

It follows, as Dr. Jarvis says, that hospitals are somewhat local in their operation, and that, in order that their benefits may be enjoyed in case

of need, they must be, in the language of the proposition, practically accessible to all the people residing within the boundaries of the district which each is intended to accommodate. A necessity so vital to the welfare of the people, becomes the bounden duty of the State. No rule limiting hospital districts to an exact and uniform area can be laid down. Indeed, it would not be possible to divide the States and Provinces in such a way that a central institution should not be more or less difficult of access from one or more remote corners of the district which it was intended to accommodate, but intelligent legislators will in most cases be able to approximately meet the requirements of the proposition, if they are imbued with a sense of its vital importance to the needs of an afflicted class of their constituents. In districting States and Provinces having large areas of unsettled, or partially settled, territory, reference should be had to the probable direction and extent of the growth of their populations, lest a sufficient number of institutions for the whole area of the State or Province should be so placed in the original centres of population as not to accommodate the subsequent settlements. Indisputable facts show that the remote inhabitants of a district must be able to reach its hospital by a journey that can be made during the waking hours of a single day, or they will not avail themselves of its benefits. Such a generalization will aid in the practical solution of this problem, for it will readily be seen that insane persons can be conveyed to a hospital by railroad from a distance of seventy-five or a hundred miles with more convenience and less expense than they can be conveyed half that distance by ordinary carriage-roads, and that the number and directions of the railroads and the character of the carriage-roads of a proposed district, should have much influence in determining its size and shape, and the situation of its hospital. The practicability of the early treatment of acute insanity will increase the number of recoveries, and proportionately diminish the number of cases of chronic insanity to be provided for. This brief discussion of this first and fundamental element of all adequate public provision for the insane, is, therefore, pertinent to the particular question under consideration.

I now come to the second proposition of the series. It is that all State, county, and city hospitals for the insane, should receive all persons that belong to the vicinage designed to be accommodated by each hospital, who are affected with insanity proper, whatever be the form or nature of the bodily disease accompanying the mental disorder. Except in some of the New England States, the ordinary poor of the United States are generally maintained in county alms-houses, and, in harmony with that practice, and mainly from mistaken motives of economy, most county authorities are disposed to provide for their insane poor as well as for their other dependent classes. The populous and wealthy counties, whose insane are numbered by hundreds, and are sufficient to fill one or more institutions of suitable size, may properly establish and maintain hospitals of their own, and thus save the cost of transportation, and secure the benefits of local employment and trade, and of easy access. It may with reason be maintained that as State legislators and officials are from their position, if not from their personal character, likely to entertain broader and more liberal views of their duty to the sick and unfortunate, and to be less under the influence of petty local strifes and parsimonies, than the officials of the subordinate municipalities, the States and Provinces should take direct charge of this class of their dependents, so peculiar in its wants and in its liability to suffer from neglect or abuse. There are

several county and city institutions the material appointments and management of which are equal to those of the average State and Provincial asylums, and it is due to truth and professional character to declare, in this public manner, that the unsatisfactory condition of others is attributable to defective means and organization, and not to the very respectable medical gentlemen who now have, or have had, charge of them. Without exception, these gentlemen appear to have discharged their duties with humanity and ability, and with very remarkable industry and perseverance in view of the difficulties and discouragements that have attended their work. City institutions for the insane are subject to the same objections as those of the county, and to the additional objection that a city will seldom, if ever, be able to afford within its limits the area of ground necessary for salubrity, privacy, and cultivation; and rather than that a city should go outside of its territory to establish and maintain an institution for its own exclusive benefit, it would be more feasible for the common authority over the city and neighboring municipalities to take charge of this sacred function of government, and administer it for their equal benefit.

To effectively prevent the peculiar abuses that are liable to creep into institutions for the insane governed by local authorities, State and Provincial statutes, with heavy penalties for their violation, should require them to be constructed, organized, and conducted, substantially as the State and Provincial hospitals or asylums are usually appointed and maintained; and should especially require them to receive, whenever the friends may desire it, the insane of the favored classes in respect to property, either as pay patients, or as free patients, supported, like all others, from the common fund of the municipality. One of these courses is pursued by all the State institutions, and there is no one feature of their organization that is as effective as this in preventing their management from falling below a liberal, curative standard. The poor will generally be well taken care of when they receive such treatment as the middle classes in respect to fortune are willing to pay for, or are satisfied with without payment, except indirectly as taxpayers. The rich will generally be sent to the corporate or private institutions, all the inmates of which are independent, and can more conveniently receive in them such indulgences as their habits and tastes require, and their means allow, than they can in large institutions, most or all of the inmates of which are a public charge. The second proposition, in theory at least, solves the question before the Section. The reception and care by every public hospital for the insane of all persons belonging to the vicinage—that is, within the hospital district—who are affected with insanity proper, includes, of course, the reception of those whose insanity is chronic, and this is believed to be the best of all the provisions for their care which have been, or are, or possibly can be made, or which have been suggested or advocated.

The movement of the insane, under this scheme, will be simply as follows: The recently insane are promptly placed in district hospitals, and there receive the treatment most conducive to their comfort and recovery. About one-half of them recover, and return to their homes and employments, or die, in the course of the year that follows their admission; the other half remain where they are without additional expense for transportation, and continue to receive care and treatment adapted to the condition of each case. Those who still give promise of improvement, are treated with that end in view, and occasionally reward perse-

vering efforts in their behalf by entire recovery of reason; those who continue to be actively maniacal, or melancholic, or who exhibit suicidal, homicidal, or other specially dangerous propensities, and the paroxysmal cases, whether simple or epileptic, receive the care that secures to each case the highest degree of comfort and safety of which it is susceptible, *and that is as necessary now as in the acute stage of the disease.* A few, perhaps ten per cent., of the annual additions to the chronic members of the hospital family, pass early into the mechanical, but not always unhappy, life of passive dements, whose bodily habits are regulated, and whose comforts are ministered to, by the order and appliances of the institution, while they engage, with more or less interest in its character and results, in such labor as they are capable of, in the wards, kitchens, laundry, and stables, and in the gardens and fields, when the sun is not too hot for their weak brains, nor the air too cold for their feeble circulations. The subjects of chronic insanity render considerable assistance in the wards occupied in part by the recent cases, and somewhat reduce the number of attendants that need to be employed; while the labor of the insane is mostly performed by the chronic patients, the recovery of those who have been recently affected is occasionally much promoted by industrial exercise, and they will here and there fall into a party of regular workers with more facility than they will work either by themselves, or in company with others whose cases are entirely of their own class. The habitual employment of a large number of patients is calculated to suggest and justify a variety of occupations, among which the recently affected may find those adapted to their respective capacities. The insane may be much benefited by labor, and may also be greatly injured by it: compulsory labor would cause the rapid and cruel sacrifice of many of the insane, both of the acute and chronic classes. The condition of the brain and the probable effects of labor upon it, should be carefully considered before each patient is put to work, and the effects of his work as carefully watched. The medical judgment that prescribes and regulates the labor of the insane, should be as able and critical as that which prescribes the drugs that are administered to them; and a medical staff accustomed to consider the conditions under which a large number of subjects of both recent and chronic insanity may labor without detriment, if not with advantage, will become more acute and just in its discriminations, and less liable to fall into injurious errors, than a staff of less experience in this particular. The extreme vicissitudes of the American climate, with its fierce summer-heats and depressing winter-colds, seem to admit of less labor by the insane in the open air than the more equable climate of Europe. If the disease be more active here than there, as many represent, our insane cannot advantageously work as much, either in-doors or out, as theirs, and yet, if such a sense of the importance of labor as a sanitary measure in treating the insane, especially of the working classes, prevailed here as appears to prevail abroad, the *systematic* employment of our patients would probably become a constant feature in the administration of our hospitals, with an improvement in the health, contentment, quietude, cheerfulness, and happiness of their inmates.

The scheme of providing for the insane of all classes in institutions situated at or near the centres of limited districts, renders it practicable for the kindred of the chronic patients to visit them occasionally, and, in addition to the immediate happiness which such visits confer, opens the way to the return of a portion of the subjects of passive, settled de-

mentia to the care and support of their families. The practice of furloughing patients, which obtains among the English asylums, has been resorted to, to a limited extent, in this country and the Provinces. If it should here become an approved measure, either of treatment or of relief of over-crowded institutions, it will be practicable and frequently resorted to only under the district system. A patient's return on furlough to his home, one or two hundred miles from the hospital, must in practice prove equivalent to a final discharge, both from the custody and from the oversight of the institution. The subjects of chronic insanity, to whom the habits of the hospital have become a second nature, are efficient aids in maintaining its discipline. Most of the recent patients, admitted one by one, unconsciously imitate the companions with whom they are thrown, and readily fall into the order of the hospital, without friction, and without special instruction or exercise of authority which many would excitedly, if not violently, repel.

In America, the insane of every degree of culture and refinement, and of ignorance and rudeness, as well as of every nationality, are received into all our institutions. The character of the institution into which a patient is sent, is mainly determined by his means, or those of his near friends who may aid him in his extremity. Each class has its conditions of happiness: The first for every class, is society after its kind; after that, the cultivated demand articles of taste and delicacy, which are an inconvenience to the ignorant; the ignorant demand the substantial conditions of physical comfort and health, which, by themselves, are bare, deficient, and depressing to the refined. After insanity has been under treatment for a year, those cases that are complicated with paralysis and other indubitable evidences of organic cerebral disease, may be classed with the cases of four or more years' duration, while cases which exhibit no evidences of organic disease may still be classed among the hopeful, and should be treated as such; but beyond the rule, which should be inflexibly adhered to, that the violent and turbulent should be entirely separated from the quiet and orderly, all rules of classification in American institutions are, and should be, regarded as generalizations which afford much aid in a proper distribution of the inmates of each establishment, but from which there must be constant departures in every effort to secure the highest comfort and the utmost alleviation of which individual cases are susceptible. As a general rule, epileptics should be placed in one or more wards by themselves, but it would be an unnecessary cruelty to subject a person of refined sensibilities, whose paroxysms are light and infrequent, to the constant observation of the painful scenes of an epileptic ward; such a patient may often be an agreeable and useful associate of the convalescents. On the other hand, culture is sometimes brutalized by dissipation and disease, and, though not physically violent, the possessor of early social and educational advantages is sometimes a most unfit associate for real gentlemen and ladies. It must be obvious, and this is the lesson of experience, that such a critical classification can be carried into more satisfactory details in the treatment of the collected insane of a community, than in the exclusive treatment of either class, or of a single division.

In estimating the necessary conditions of the best provision for the subjects of chronic insanity, it should be borne in mind that this is precisely the same disease in its nature and phenomena as recent insanity: they differ only in duration, in the proportion of cases of passive dementia, and in the prospect of restoration. It follows that the active

forms of chronic, mental disease require precisely the same treatment as the recent. The protection of society and of the individual, and the mitigation of the pains and privations of disease, are as much demanded in the case of the chronic maniac, whether his mania be constant, recurrent, periodical, or epileptic, as in that of the recent; and it stands to reason that a medical staff, constantly accustomed to treat recent insanity with the expectation of curing it, is likely to be better prepared, both by knowledge and habit, to treat chronic disease for its alleviation, than one whose professional efforts in the exclusive treatment of chronic disease are very rarely rewarded by a full restoration.

The theoretical grounds of the rule that all public institutions should receive the subjects of both recent and chronic insanity, are sustained by the crucial test of experience. Nearly every institution for the insane in Christendom is to-day occupied by cases of every variety, duration, and manifestation; from the last admitted, in which the outbreak occurred but a short time ago, to the most hopeless case of fatuity. The exceptions are a very few—not, I think, as many as half a dozen altogether—which are occupied exclusively by chronic and presumptively incurable inmates; I know of none which receives only recent cases and discharges them as soon as they become chronic. The presence of recent and chronic cases in all institutions is, of course, due in part to the retention of cases which were admitted when recent, and which have passed to the chronic state; but it is by no means wholly due to a circumstance so natural and purposeless. Not only was the subject of the care and treatment of the victims of chronic insanity fully discussed, both in Great Britain and on the continent of Europe, long before the question became an urgent one in this country, but, after trying various experiments in separating, to a greater or less degree and in various ways, the acute from the chronic cases, the Europeans have all, I understand, come back to what in England is called the *public-asylum*, and here the *State-asylum, or hospital, system.* In fact, if the public institutions for the insane in the United States and the Provinces of the Dominion were to be distinguished by the character of their inmates in the respect under consideration, they should be styled asylums for the subjects of chronic or incurable insanity, and if the recent and chronic cases were to be separated, the most numerous class (the chronic) would naturally take the present institutions, which are much too large for the recent, and the pertinent and pressing question of the day would then be *the best provision for the recent or acutely insane.* Estimates kindly furnished me by 27 superintendents of the United States, show that, on an average, $12\frac{1}{2}$ per cent. of the cases of insanity in 22 States are of less than one year's duration, and the remainder chronic. Five of their superintendents estimate the average ratio of recent to chronic cases of insanity in the Provinces of Canada to be $7\frac{8}{10}$ per cent. As only five of the States make full provision for all their insane, in institutions having a resident medical head, it may be that the ratio of recent to chronic cases, under treatment in them, is a little greater than in the whole insane population of those States; but I am more inclined to think that the estimates of recent cases are too high, and will not be borne out by the results of treatment. The proposition is not only sustained by the practice of the institutions of both the old and new worlds, but by the authority of the ablest and most experienced men in the specialty; among readers of the English language the names of Dr. Bucknill and Dr. Robertson, of England, and Dr. Earle, of this country, are best known in this connection.

Perhaps a full consideration of the plan of providing for the subjects of chronic insanity, now as fully set forth as the time allowed me will permit, should embrace answers to the objections that have been, or may be, made to it. It has been said that the retention of chronic cases in the hospitals in which they have been placed, brings no direct relief to the wretched lunatics in the county alms-house receptacles. It does not, except by arresting all additions to their number, which would certainly be a great and happy achievement; but the objection is answered by a simple declaration of the obvious truth, that it is less expensive and in every way more feasible to provide for the alms-house insane in district institutions than in any other proper way. It will cost less for the necessary enlargement of buildings and their appointments, and for transportation. If a sufficient number of district institutions already exist, they can be enlarged both so as to retain all the patients whom they do not cure, until they die, if their condition require it, and to receive the alms-house patients at less expense than would be incurred by providing for them either independent central, or district, asylums of a proper kind; and if there are not enough district institutions to make them practically accessible to all acute cases, they certainly should, for reasons that have been given, be provided as rapidly as possible with accommodations for all the chronic cases of the vicinage.

It has been said that the States (I do not recollect that it has been said of the Canadian Provinces) will not incur the outlay necessary to provide institutions with such appointments and management as are deemed necessary for recent cases; but this declaration is shown to be unfounded by the activity and liberality which are displayed at this moment by the greater number of the leading States, in establishing excellent district institutions for all their insane, of both the acute and chronic classes. Five States have provided for every case within their borders not preferably provided for by friends, and others will soon have discharged the same duty. An editorial table in a recent number of the American Journal of Insanity shows that the total present and prospective capacity of the institutions for the insane in the United States is for 35,325 inmates, at a cost, according to a table prepared by Dr. Conrad, of the Maryland Hospital, of at least $35,000,000, with an annual expenditure, at this time, for maintenance, of $5,000,000. This has mainly been accomplished in the last half of that century of our national existence which has just terminated, scarcely as many as the odd 325 of the number now under treatment having been provided for fifty years ago. I am sorry to be compelled to acknowledge that there is not yet sufficient hospital provision for the insane in the United States, and that in a few instances that which exists is seriously defective in material appointment and organization; but I cheerfully submit the work of the first century of the Republic in the personal care and legal protection of the insane, to the judgment of our impartial psychological brethren abroad, with much confidence that it will be deemed to be indicative of a high degree of enlightenment and liberality on the part of the American people who have sustained it with their means; of true science and humanity on the part of American psychologists; and of genuine Christian benevolence on the part of the noble men and the philanthropic woman,[1] who have executed it with the best efforts of their heads and hearts.

As the third, fourth, and fifth propositions relate to the means and

[1] Miss D. L. Dix.

modes which render the approved and prevailing plan of providing for the subjects of chronic insanity practicable and successful, I shall briefly consider them together. The propositions of 1851 and 1853, referred to in the series of 1866, and quoted in the foot-note to page 1128, express in considerable detail the essential conditions, both material and administrative, of the successful treatment of the insane, and, being of acknowledged authority, have prevented many costly errors of ignorance in establishing the institutions of the country, and have efficiently promoted the general uniformity and excellence of their management. With the experience of the quarter of a century during which those propositions, 40 in number, have been in force, they are, with slight modifications, considered as judicious and binding as when they were put forth, except that a change of circumstances has rendered it necessary to depart from two or three of the rules which use arbitrary numbers in expressing their requirements. The increased numbers of the insane to be provided for, and the larger ratio of the chronic to the curable inmates of our institutions at the present time, as compared with that of twenty-five years ago, have rendered it necessary and admissible to treat a much larger number of patients in one institution than was then considered proper. Like many institutions of government, education, and business, those for providing for the insane have grown upon our hands until they have become much larger than was anticipated when those propositions were framed and adopted. Other things being equal, the evidence of experience and authority shows that hospitals having 500 patients are managed as advantageously to their inmates, and quite as economically, as those having half that number; and there is nothing in experience, nor, to my mind, in theory to show that hospitals containing a still larger number of inmates, "embracing," in the language of the fifth proposition of the series of 1866, "the usual proportions of curable and incurable insane in a particular community" are not equally well managed. Of course it is necessary, and, I believe, conducive to the welfare of patients and the advancement of the specialty, that the ratio of staff-physicians should not only be proportionate to the number and character of the patients, but that the physicians should be charged with more authority and responsibility than they usually possessed twenty-five or more years ago. That they should be men of ability, liberal education, and sound principles, no one will deny. It does not appear to me that the number of assistant physicians required in large institutions for the insane can be determined by a rule of universal applicability, but I think that a proportion of one to one hundred cases of active disease, whether acute or chronic, and one to two hundred chronic cases that are ordinarily quiet and orderly, will, on the one hand, afford no opportunity for the rust and vices of idleness, and will, on the other, be sufficient for the performance of every useful professional office in the medical and moral treatment of the patients, with time for the relaxation necessary to the maintenance of cheerful health, and for professional and general improvement.

The prevalent overcrowding of institutions for the insane, is highly prejudicial to the welfare of their inmates. Not only should this be avoided by the provision of ample room for the number of cases under treatment, but the facilities of classification or ward separation possessed by institutions which receive all the insane of a community, should considerably exceed those ordinarily provided, in order that, in addition to the usual classification, based mainly on conduct and the activity of disease, there should

be sub-classes of epileptics, of dipsomaniacs, of regularly working patients, and of patients who are too demented, or who, though able, are too indolent, to work—each of these classes requiring some special provision and treatment.

In enlarging district institutions, in addition to extending the original structure as far as it will admit, I think that one or more detached buildings or wards may be desirable in effecting all useful purposes of subdivision. I certainly see no objection to them for the use of the quiet classes of agricultural patients, if not placed too far from the main structure, if the topography of the grounds favor the erection of such wards, and if it be thought otherwise desirable; but I should always consider it an indispensable condition of good management, that the assistant physician having immediate charge of the inmates of a block or group of blocks, should have such a residence that he could not only conveniently see his patients often, but that he could be readily consulted at all hours of the day and night. In some cases, the fitness of accommodations might be most economically and conveniently secured by the erection of new and improved buildings on the same grounds with old and imperfect ones, and the devotion of the former to the recent cases and their suitable associates among the chronic, and of the latter to the most hopeless cases or to those belonging to the collateral classification which I have recommended.

When a district institution contains as many as 600 patients of both sexes, and the number is likely to considerably increase, a second complete set of hospital buildings should be provided in the same neighborhood, and, if practicable, on continuous grounds, and the sexes separated by retaining one in the old buildings and placing the other in the new. The buildings for each sex should be separately inclosed, and not much less than half a mile distant from each other, unless a hill or wood should present a natural barrier to the view and hearing of one from the other. The two sets of buildings being in the same neighborhood, patients of both sexes can at the same time be accompanied to and from them by the same friends or officers, and the same relatives can visit patients of both sexes by one journey, which will not unfrequently be both a convenience and a saving of expense. The employment of each sex will conveniently and economically supplement that of the other. The men will raise vegetables, milk, etc., for both establishments, and the women may do the washing, mending, etc., for the men as well as for themselves. The separate care of each sex will render admissible many relaxations of the restraints to personal liberty that prudence requires when both sexes occupy connecting wings of the same continuous structure. After the separation, the superintendent may remain in charge of both establishments, with an adjunct in immediate charge of each, or there may be an independent superintendent of each, under the same board of management, as circumstances may render most expedient.

All public buildings, particularly those belonging to a government of the power and dignity of a State or Province, should present just claims to architectural fitness and taste. Edifices occupied by the insane should be at least neat and cheerful in their appearance; and their construction of durable materials in the most enduring manner will prove most economical in the end. Cost should be held subordinate to every essential sanitary provision, as drainage, ventilation, the supply of light, heat, and water, and abundant room and means of classification; and just in proportion as such provisions are subordinated to necessary cost in the construc-

tion and fitting up of buildings for the insane, do these become custodial receptacles which deny to their inmates the benefits of hospital treatment. There is, however, some incongruity in providing highly ornamental and costly structures mainly for the treatment of the insane poor, most of whom have little or no æsthetic capacity to appreciate and be benefited by the outlay; and it may be feared that the taste and ambition of legislatures that at one period authorizes the high embellishment of hospital structures at considerable cost, will at another be accused of extravagance, and that, in the strifes of political parties, such expenditures will be made the pretext, if not the reason, for withholding appropriations for the most necessary purposes. Happily, the first cost of the essential provisions for the most humane and beneficial treatment of the insane of the dependent classes, has now been determined by a wide and varied experience, and is found to be much less than has been sometimes expended for the purpose, and not to exceed the means of any State. What the States and Provinces have already accomplished in this direction, and most of it in the short period of less than fifty years, while they have been at the same time not only providing their capitols, court-houses, penitentiaries, and other buildings that directly appertain to the necessary functions of government, and also making considerable outlays for institutions for the blind, for the deaf and dumb, and for feeble-minded youth, affords as positive a guaranty as anything that lies in the future can, that at no distant day all of them will adequately care for all their insane poor, as well as no little excuse for what appears to impatient benevolence and sometimes unpractical science, to be inexcusable tardiness in the discharge of their imperative duty.

Discussion on Dr. Nichols's Paper.

After the reading of the preceding paper, Dr. Isaac Ray, of Philadelphia, said:—The increase of insanity among us has led to much inquiry as to the best means of caring for its subjeets, who are mostly of the indigent class, with the greatest degree of economy compatible with a proper regard to their comfort and cure. One of the conclusions arrived at by many intelligent men, some of them superintendents of our hospitals for the insane, is that the larger our hospitals, the more cheaply they may be built and maintained. This conelusion I have always regarded as unsound, and the more the experiment has been tried, the more it has confirmed me in this opinion. True, an institution for 200 patients would, undoubtedly, eost less, proportionately, than one for 40 or 50 patients, other things being equal. But the rule is not absolute. There eomes a point where the economical result is reversed, so that the larger the hospital, the more expensive it will prove. Indeed, it would be hard to show how increase in size can be followed by decrease in expense. A well organized hospital-staff should consist of a superintendent, two assistant physicians, a steward, matron, and a force of attendants equal to one to every five or ten patients. A farmer, and more or fewer assistants, will be needed for outside work. Not less than this is required in a hospital of 300 patients. Consequently, a hospital for 600 must require double the number of assistant-physicians, and double the number of attendants, and of indoor and outdoor servants. The matron and steward will each require a helper. Where or how the eost of maintenanee is diminished, is not very obvious. True, the eost of one superintendent is supposed to be saved, but, unquestionably, the larger the establishment the larger would be the salary of the superintendent, and as more eare and responsibility would be thrown on the assistants, their compensation would naturally be increased. So that little, if anything, could be saved in

that direction. Besides, I believe, it is generally understood among those who have had some experience in the financial history of institutions requiring the expenditure of more or less money, that the practice of economy is much affected by the amount of money disbursed. The smaller it is, the more frugally it is spent. In the daily handling of large sums, there comes, as a result of such familiarity, a sort of contempt for small sums not likely to produce the strictest economy. This is human nature, and implies no lack of honesty or sagacity. Though not very familiar with the reports of our hospitals, of late years, yet I have the impression that our largest hospitals show no decided advantage over the smaller, in the cost of maintenance. Any little difference in their favor may be, very likely, the result of other causes. According to the report of the Willard Hospital, for the year 1874, the average cost was $3.17 per week, if I recollect rightly, which is little less than it is in some of our smaller State hospitals. And yet it is supposed that in the former the patients are all of the kind that can be properly maintained at the least expense. And this figure is likely to be increased in future years, by the repairs and renewals, always a formidable item in the expenditures, and none the less, certainly, where the buildings are cheaply constructed, and all the appointments of a makeshift kind.

Nor do I see how the expense of construction can be diminished by the plan much favored just now, of having the hospital consist of several buildings, separate and independent, scattered over the premises, instead of a single structure receiving all the patients under its roof. The idea that anything is gained by this mode of construction is such an obvious fallacy that one hardly knows how to meet it. It certainly has always been supposed that, in building, the less you have of wall and roof, the less will be the first cost; and if that be so, it is self-evident that 20 or 30 patients can be more cheaply provided for in a hall, in the usual way, than in a building designed only for them. Nor does it need any special proof to show that the expense of warming and ventilating several detached buildings must be far greater than would be needed for a single one of equal capacity. The fact is obvious at sight. In short, the clamor against "palatial" structures, to use the popular phrase, is little better than claptrap, thoughtlessly used by people supremely ignorant of the cost of building at the present day, as well as of the peculiar requirements of a hospital for the insane. As the result of my own observation and experience, I am convinced that four hospitals for 300 patients each, can be both built and maintained at a less cost than one for 1200 patients, equal provision being made in both cases for the kind of care to which the insane, even in the lowest grades of the disease, are entitled.

I doubt, however, whether it is possible to have, in these mammoth establishments, certain qualities of administration indispensable to their highest purposes. The animating spirit, the close and thorough supervision, inspiring, guiding, correcting every movement, and essential to our highest idea of hospital management, will be but feebly manifested under such conditions. The patient is but an atom in the great mass around him, losing the attributes of humanity, sane and insane, in the technical character of patient.

Contending as I now do, and as I always have done, against the establishment of large hospitals, I cannot give an unqualified approval to Dr. Nichols's paper. With this exception, however, I heartily concur in all his conclusions.

Dr. Thomas S. Kirkbride, of Philadelphia, said:—I am sure that we must all appreciate the value and importance of the excellent paper which we have just heard read. There is little in it with which I do not agree entirely. On one point, however, I must confess that my views differ from those expressed by my excellent friend, and that is, in regard to the best size for hospitals for the insane. We all know that this is a point on which there has, of late years at least, been a difference of opinion in the Association of Medical Superintendents. As it now stands, indeed, it is the only one of our many propositions that has not received an unanimous, or very nearly unanimous,

approval by the members. I still believe that the original proposition was right. I believe that the size then recommended is really better than any other, but I am also fully aware of all the arguments that can be brought to justify much larger hospitals, especially those of *expediency* and even *possibility.* It is fully shown by reliable statistics, as I believe, that the people of the State will derive more benefit from several small hospitals in different parts of the State, than from one large one at a central point; and I think that it will also be found that the former can be provided with quite as small an expenditure of money, and can be carried on at no greater eost per patient.

Dr. Nichols has recommended the plan, which has now been fully tested, and which, even by the first decision of the Assoeiation, allows as many as 500 patients being collected in one vicinity; and this is by having separate hospitals for the sexes. This plan I feel that I have a right to say is no longer an experiment. A trial of sixteen years under my own observation has shown that, in every respect, it is a most valuable arrangement, having many advantages and no disadvantages. It has also received unqualified approbation from many other distinguished psychologists in addition to Dr. Niehols. I am aware that it has been said that, while I argue in favor of hospitals for 250 patients, practically, I have been providing one to accommodate twice that number. This, however, is a mistake. The Pennsylvania Hospital for the Insane, at Philadelphia, is really made up of two entirely distinct hospitals, one for each sex, and it has been so, as already said, for more than sixteen years. Both hospitals have the same board of managers, and, for reasons not neeessary to detail here, have always had the same physician-in-chief and superintendent. It is anticipated, however, that ultimately each will have its own separate superintendent, and that the only connection between them will be the board of managers.

Now, what we have done, is exactly what I would propose for any hospital. First build your hospital for 250 patients. This will commonly be occupied by both sexes. When this is filled, or nearly so, build another for a similar number of patients. Separate the sexes; have distinct organizations—all on the same tract of land, but with entirely separate pleasure-grounds. There may be the same water-works, gas-works, bakery, machine-shop, and other common arrangements, that will add to the economy of the institution. This provides for 500 patients in one locality, and yet conforms to the original proposition of the Association. I do not propose entering into any extended diseussion of the reasons why I believe that these smaller hospitals have advantages, but there is one that I cannot avoid referring to, and that is the personal intercourse which a superintendent is able to give to his patients, when their number is not so great as to prevent his paying daily, or very nearly daily, visits to each. I believe this to be one of the most important of all his duties, and one which generally, if he is rightly constituted for his position, *no one can do for him.* It is true that an assistant may be superior to his chief in this respect, but this is not to be anticipated, and if it is so, the assistant ought to have charge of a hospital himself. Two hundred and fifty patients, or about that number, are as many as any superintendent can visit daily, with tolerable satisfaction to himself and to them.

Now, I do not wish to be misunderstood in this matter. I still think, as the Association at first thought, that this size of 250 is the very best, but I do not mean to say that no other is admissible. I am well aware how much easier it is to get an appropriation for the extension of a hospital, than for the building of a new one. What I mean to say is this:—Build your hospitals, in different parts of a State, of a capacity for 250 patients, and in sufficient numbers to accommodate *all* your insane, *if you can do so.* If you cannot do this, and yet can build single hospitals for 500, 700, or even 1000 patients at one point, by all means do so. The hospitals you must have at all hazards. If you cannot get what I regard as the best arrangement, come as near to it as you can, let the size be what it may.

The President, Dr. John P. Gray, of Utica, said:—I should object to putting buildings half a mile apart, if for no other reason, because such an arrangement would render it difficult, if not impossible, for the superintendent to consult constantly with his subordinate officers. I was chairman of the commission which located the Willard Asylum. We found the point on the lake the most desirable place for the main hospital building; the building now called the "branch," and more than half a mile away, was then erected; it was the old State Agricultural College, and was subsequently remodelled to receive patients. But there is a resident physician in the "branch," as there are in other separate buildings, since constructed, and these physicians, for all practical purposes, exercise the power and control of resident superintendents, for the communication between these distant structures and the main hospital-building is by telegraph. Although that is an institution for the subjects of chronic insanity, there are five medical men, a superintendent and four assistants, for a thousand patients—and they are needed. Though as a commissioner I voted to place the main building on the lake, I did not like the feature of having buildings half a mile or more apart. In this instance it seemed a necessity, though undesirable.

As to the other question, as to the number to be accommodated in a single institution, or under one superintendent, there is great difference of opinion. Some think it just as practicable to have 2000 as 1000, or less. I think that 600, the maximum of the proposition of the Association of Superintendents, passed a few years ago, is as many as should be under one superintendent, even if the buildings be separated, and each have a resident physician. In England, some of the best public institutions are larger than those in this country, and, according to Dr. Bucknill, in his recent letters on American Asylums, published in the Lancet, are not as well supplied with medical officers. That at Wakefield, the West-Riding Asylum, standing at the head, has 1800 patients.

In reply to the criticisms of Dr. Kirkbride on the qualifications of assistant physicians, I think it important to have assistants who have had hospital experience. I should object to taking young men just out of a medical college, and without medical experience, and putting them in such responsible places. Dr. Kirkbride's remarks as to qualifications would apply with double force in an asylum where the buildings were separated.

INDEX.

THE END.
